The *Times* supports the opposite opinion. It is making desperate efforts to counteract the influence on the public mind which this Report, when understood, cannot fail to exercise. With an air of candour, calculated to mislead, it professes the intention to publish an analysis which shall give both sides of the question, and begins with the evidence favourable to the Armstrong case. The review of this side of the question is executed with the talent which characterizes the writing in that journal, but the spirit of partizanship is apparent in every line. Extracts from the evidence favourable to the system are skilfully grouped and brought into relief, so as to impress on the reader's mind *a priori* the conviction that the country is deeply indebted to Sir William Armstrong, that he is an engineer and artillerist of transcendant genius, and that, up to the time when the Armstrong system was adopted into the service, no other inventions or ideas were deserving of the attention of the Ordnance Department. This is the delusion which has so long been practised. To remove it, is one of the duties we undertake; and it is one, which, with a fair exposition of the evidence furnished by the Parliamentary Report, it will not be difficult to accomplish. The points raised by the investigation are so multifarious that, to avoid confusion, we deal with them separately; and, summing-up impartially, we apply to each the evidence which bears upon it.

Advent and Influence of Mr. Armstrong.

"As almost the whole of the expenditure inquired into (says the Report) was incurred upon Armstrong guns and ammunition, the Committee deem it necessary to commence with a short history of the introduction of that system of ordnance into Her Majesty's Service."

From that history we extract, in chronological order, the following narrative of events:—Mr. Armstrong first appeared upon the scene of his future celebrity, in December, 1854, when he had an interview with the Duke of Newcastle, and obtained from him an order for six guns for trial. The first of these guns, a 3-pounder, was delivered in July, 1855. The Ordnance Select Committee made experiments and a report, which, though qualified, was, in the main, favourable to the gun, and desired further experiments. The gun was rebored up to a 5-pounder, and in December, 1856, was tried near Newcastle in the presence of Colonel Eardley Wilmot, who reported "that at 1,500 and 2,000 yards the gun had made remarkably good practice."

In January, 1857, a second gun was ordered, an 18-pounder, and reported ready on 1st July, 1857; but the trial was delayed, owing to Mr. Armstrong's absence on the Continent, until 26th January, 1858, when experiments were made with it in competition with a service 32-pounder gun. The 5th February, 1858, the Ordnance Select Committee reported the result as highly satisfactory. The 25th February, 1858, two 18-pounders, and on the 13th April, 1858, one 12-pounder and 400 projectiles for the 18-pounder, were ordered for further experiments. About August, 1858, General Peel called upon Col. Lessing for a report on all the experiments that had been tried on rifled ordnance; for which purpose, early in September, 1858, the "Special Committee on Rifled Ordnance" was appointed, with Colonel Mitchell, R.A., as President, and Captain Andrew Noble, R.A., as Secretary. This Committee came so the conclusion that it was not expedient to incur the expense of trying further experiments with any guns but those of Messrs. Whitworth and Armstrong. The 30th September, 1858, a letter was addressed from the War-office to Messrs. Whitworth and Co., expressing the wish of the Committee on Rifled Cannon to visit their establishment at Manchester. The 21st September, Messrs. Whitworth replied, and offered to afford every facility to the Committee to inspect their works. The 2nd October, Colonel Mitchell wrote to Messrs. Whitworth to inform them that the Committee would not visit their establishment till the 5th or 6th November, and they purposed visiting Mr. Armstrong's first. The 30th October, 1858, a letter was addressed from the War-office, by order of General Peel, to Messrs. Whitworth and Co., suspending the preparation of the shell and shot ordered the 1st October, as the Committee on Rifled Cannon had a sufficient supply, and it was not probable that any more would be required.

Between September, 1848, and January, 1859, experiments were made by this Committee, with the Armstrong and Whitworth guns in competition. The Armstrong guns fired 50 rounds of solid shot, segment shells, and shrapnell, and the Whitworth only 9 rounds of solid shot and shell, without bursting charges, Mr. Whitworth not having received notice that firing live shells would form part of the programme. In January, 1859, from the result of these experiments, the Select Committee on Rifled Cannon reported against the Whitworth, and in favour of the Armstrong system, and recommended the latter to be adopted for the field guns of the service. Soon after this report, Captain

Noble became a partner in the Elswick Company, which was formed about this time.

The 18th December, 1848, Lord Derby, in a letter to General Peel, said that "he should rather doubt the expediency, in the present infancy of the Armstrong invention of pressing for the supply of a large number of guns." He suggested that the "first order should be confined to 32-pounders, and that the construction of heavy guns should be deferred till they had been more tested." This prudent recommendation was disregarded.

The 15th January, 1859, Mr. Armstrong assigned his interest in all patents for, and improvements in, the manufacture of ordnance to the Government. The Secretary of State refused to submit these patents to the Committee, an Act of Parliament having been passed to keep the specification secret. Previously to these events, a guarantee was given to Mr. Armstrong, "that he should not be a loser by the expenditure of £12,000 on a plant sufficient to enable him to turn out 100 guns a-year." The 16th January, 1859, a guarantee to the same effect was given to the Elswick Company for £50,000, which was soon afterwards increased to £60,000. The 23rd February, 1859, Sir W. Armstrong was appointed Engineer of Rifled Ordnance, with a salary of £2,000 for ten years, and about the same time received the honour of knighthood. In September, 1859, a Committee was formed to decide upon the "best calibre for naval guns." It was composed of Lieutenant-Colonel George, the President of the Ordnance Select Committee; Captain Sir W. Wiseman, Vice-President of the same Committee; Sir W. Armstrong, the Engineer of Rifled Ordnance, at the Royal Gun Factory; and Captain A. Noble, a partner in the Elswick Company, as Secretary.

Soon afterwards this Committee "approved of the adoption for the naval service of Sir W. Armstrong's 40-pounder, and also recommended that the 6-pounders, 12-pounders, 100-pounders, and 200-pounders should be guns of Sir William Armstrong's construction." (Captain Wiseman's Evidence, pp. 165, 166, 167).

This "Naval Gun" Committee having thus promptly reported in favour of the adoption of of the Armstrong ordnance for all purposes, and completed the work for which it was formed, was dissolved before the close of January, 1860.

After a short interval, on the report of this "Naval Gun Committee," the Ordnance Select Committee reported in favour of "the adoption, for Her Majesty's Service, of all the guns up to 110-pounders; but (says the Parliamentary Report) several of the larger guns were introduced into the service by order of the Secretary of State without waiting for the report of the Ordnance Committee." (Captain Wiseman, p. 169.)

In October, 1859, the guarantee to the Elswick Company was increased to £85,000, and Government undertook to keep the Company in full work.

The 4th November, 1859, Sir W. Armstrong became superintendent of the Royal Gun Factory for rifled ordnance.

Thus, with careful preparation and the cordial co-operation of a great public department, and its subordinates, during a period of five years, were events, contributing to the adoption into the servce of the Armstrong system of artillery—to the aggrandisement of its projector, and the sudden wealth of himself and his coadjutors, partners in a commercial company—first skilfully and patiently elaborated and then, in hot haste, crowded upon each other, till the work was consummated to the exclusion of all competitors.

Everywhere the barriers of official etiquette and obstruction were thrown down before Mr. and Sir William Armstrong, his measures were in all directions a complete success, and he found himself master of the situation, without an opponent, with the entire control of his proceedings in his own hands, and the national treasury at his command.

We shall, in due course, show from the evidence, how the Armstrong party obtained this commanding position, and contrast it with the contemptuousness, indifference, and humiliating treatment, which the evidence shows every other manufacturer and projector of ordnance met with in the Government departments.

ENGINEERING SURVEYING.*

Not many years ago the acquirement of knowledge by mere study alone, was a difficult task from the paucity of books of a sufficiently lucid and comprehensive character to meet the requirements of the student. Thus, many an individual, now standing high in his profession, can tell a tale of struggle and hardship, of difficulties overcome and obstacles surmounted, in the pursuit of that knowledge on which his future depended; while adverse circumstances precluded its acquirement from any source save books; most of them expensive, and nearly all obscure to the neophyte. Professional education is not yet all that it should be. Every man who has attained the meridian of life can bear testimony to the waste of long years in learning that which never served a good purpose afterwards. We have perhaps, all alike waded through books, fifty of whose dreary pages failed to convey the information which might have been condensed within the compass of ten, and pored over volumes until the eyes grew dim and the brain sick, in the weary struggle to extract that knowledge which it seemed the darling object of the writer to surround with a veil of mystery and doubt. Perhaps the text-books used twenty years ago were sound enough in their conclusions and accurate in their calculations and formulæ; but they seldom or never were valuable to the student without the assistance of a master. Applied mathematics, mechanics, and, perhaps natural philosophy, in so far as it embraces hydraulics and pneumatics, may be ranked among the exact sciences; and there is no good reason why a theoretical knowledge of each, as far as it applies to civil and mechanical engineering, architecture, and kindred pursuits, should not be obtained from books without the aid of any oral instruction whatever. It is certain that a judicious course of reading, with carefully selected library, will do much to facilitate the subsequent labours of the student. Many a lad has entered on a regular apprenticeship, so thoroughly self-prepared in all that related to the theory of the profession in which he desired to become an adept, that he has been at once capable of performing many important duties with credit to himself and advantage to his employer. Unfortunately, the works which can be perused with advantage, without the aid of one already skilled in the questions of which they treat, are very far from numerous. They are more abundant than they were in our fathers' days; and even in this admission there is comprised much for which we ought to be grateful. Scientific literature is cheap, and for the most part good; but there is wide scope, notwithstanding, for improvement in the text-books to which the engineer in the full tide of practice will turn for information, as well as the young man commencing his studies. The difficulty experienced in arriving at the exact meaning which an author intends to convey, is usually a measure of his industry or of his skill in imparting information. Careless writing, or too condensed a method of treating a subject, equally add to the perplexity and mental labour of the reader: the author sparing himself at the expense of the student, who cannot be supposed to have a skilled instructor always by his side to supply that which is wanting in the text. How many men write complete, clear, and excellent books, alike comprehensive and comprehensible, we cannot pretend to say; but, judging from the volume now before us, Mr. Merrett certainly deserves to rank among the number.

Commencing with a slight history of the origin of land-surveying, Mr. Merrett carries his readers back to Ancient Egypt, points out that the annual inundation of the Nile destroyed the landmarks, and therefore occasioned a demand for some accurate method of ascertaining the original boundary of individuul property, and goes on to show, that this object was carried into effect in the most efficient manner by Euclid. Thus claiming for the art of land-surveying an antiquity which places it amongst the oldest of the applied sciences. Subsequently; treating of the duties of the land-surveyor, and pointing out their importance from a legal aspect, he brings us to the conclusion of a very readable introduction, in the course of which he explains a few of the principles involved and the nature of several of the instruments employed.

The main portion of the work is divided into six parts, the first of which is devoted to the consideration of that geometrical and arithmetrical machinery—such as logarithms, decimals, geometrical drawing, the properties of angles, parallelograms, &c.—on the accurate working of which, all the operations subsequently described depend for success. This department once mastered—no difficult task, for the definitions are clear, and the explanations and illustrations lucid and ample—the student will find in the second part, an able treatise on the practice of land-surveying, in the simplest sense in which the phrase is understood; to which is added a chapter on plane trigonometry. In the year 1801, and reign of George III., an Act was passed, called the General Enclosure Act; since which there are five Acts of Amendments for the Enclosure of Commonable and Waste Lands, and Allotting Land in lieu of Tithes; Common and Cottage Rights, the claims for which are various in different parishes. Mr. Merrett has a chapter on this rather difficult question of enclosures, the perusal of which will leave little doubt as to the proper course to be pursued by the surveyor in all cases to which the Acts apply.

Part Third treats of levelling, both in a general sense, and more fully as applied to the setting out of railway lines, roads, and canals. Instructions are given at length for making maps, plans, and sections in strict compliance with standing Parliamentary orders. The rules laid down for the setting out of railway curves are, without exception, the simplest and best we have ever met with. Divested individually, of even an approach to complexity, they are totally free from that mass of algebraical formulæ which so frequently renders very simple questions obscure in the extreme to any one but an expert. It is, perhaps, too much the fashion, lately, to clothe very ordinary arithemetical operations in a garb of mathematics, which can serve no possible end excep

* "A Practical Treatise on Land and Engineering Surveying." By H. S. Merrett. London: Spon, 1863.

ministering to the vanity of the writer. Mr. Merrett's book is free from this vice; no trifling recommendation in our eyes.

The calculation of quantities generally, for estimates, forms the subject of the fourth section. The first great item of expense in the construction of a railway is land, which always bears an exceptional value when required for such a purpose. Next to this, we may rank tunnels, cuttings, viaducts, bridges, and embankments. Without tolerably accurate estimates of the amount of work involved in such undertaking, it is hopeless to imagine that they could ever be brought to a successful conclusion in a financial sense, whatever the engineer might accomplish. Mr. Merrett is well aware of the importance of this question, which he treats accordingly at some length and with considerable skill; all the problems being easily worked out by his rules, with little labour and very few figures, the results obtained being, for the most part, sufficiently near the truth to answer every practical requirement. The chapter is not confined to the consideration of earthwork. On masonry, brick, iron, and timber measuring, our author imparts much valuable information within the compass of a few pages. The fifth portion of the volume is a treatise on the instruments used in surveying, plotting, and levelling, and their use; while the sixth and last, consists of a series of useful tables for reference, carefully selected and conveniently arranged. The volume is illustrated by no fewer than forty-one large folding plates.

Could we conclude here, we would be well satisfied; but we would scarcely do our duty did we not point out that many inaccuracies exist in the style of composition, and the language made use of by the author. It is not, perhaps, quite fair to expect a professional man, in considerable practice, to write with much care, or devote that time to a work which is almost indispensably necessary to secure strict elegance of diction. Future editions will, we doubt not, be free from these imperfections; which are of the less moment, in that they seldom or never obscure the author's meaning. As it stands, the book is a thoroughly good one, calculated to supply a great want, and cannot fail to be equally useful to the student, the practical surveyor and engineer.

BIRMINGHAM INSTITUTION OF MECHANICAL ENGINEERS.

The general meeting of the members was held on Thursday, the 5th inst., at the house of the Institution, Newhall-street, Birmingham, Sampson Lloyd, Esq., in the chair.

The Secretary (Mr. W. P. Marshall) having read the minutes of the previous meeting, a large number of new members were elected; and the officers of the Institution were nominated by the meeting for the next annual election.

The first Paper read was a "Description of the Cornish Pumping Engine, with Wrought Iron Beam, and the Pit Work, at Clay Cross Colliery," by Mr. William Howe, of Clay Cross. The engine is one of large size, erected for the drainage of the entire colliery at a single central pumping station, in place of a number of smaller pumps previously situated in different portions of the colliery, and most of them worked by the winding engines. The new engine is made powerful enough to allow of considerable future extension of the workings, having a cylinder of 84 in. diameter, and 10 ft. stroke. The beam was constructed of wrought iron, instead of cast iron, in consequence of the fatal accident at the Hartley Colliery by the breakage of the cast-iron engine beam; it is composed of two large wrought-iron slabs, each rolled solid in one piece, 36 ft. long, deep in the centre, and 2 in. thick throughout, the two slabs being securely braced together by strong cast-iron distance-pieces bolted between them, and a wrought-iron plate connecting them at the bottom in the centre portion, which render the beam thoroughly stiff laterally. The main centre gudgeon is fitted through a strong cast-iron centre-piece, which has a turned boss at each end, fitted into bored holes in the wrought-iron slabs; and large cast-iron washer plates are fixed to the beam slabs and bored through for the bearings of the other gudgeons, which are keyed in them: the entire beam weighs 32 tons. The pit work consists of a lift pump at the bottom of the shaft, which is 418 ft. deep, and two plunger pumps in the upper portion, all 18 in. diameter and worked by the main spears, which are of very strong construction, secured at the joints with wrought-iron straps fixed by turned bolts through bored holes. The quantity of water to be raised by the pumps fluctuates greatly at different seasons, and at the present time a slow speed of working the engine is sufficient to keep the colliery clear of water.

The next Paper was "On the Processes and Mechanical Appliances in the manufacture of Polished Sheet Glass," by Mr. Richard Pilkington, jun., of St. Helen's. The manufacture consists of three processes—melting and blowing, flattening, and polishing. In the melting furnace a portion of the melted glass is collected on the end of the blowpipe, and blown out into a globe, which is elongated by swinging into the form of a long cylinder. In the next process this cylinder is cut open down one side, flattened out into a sheet of glass by exposure to heat in the flattening kiln, and then annealed by gradual cooling. The sheets to be polished undergo a preliminary process of smoothing, two sheets of glass being worked one upon the other by hand with emery and water between; and as their surfaces become obscured, finer and finer emery is used, until they are smoothed free from all defects. The polishing is done by machinery by a number of heavy rubbers supplied with red oxide of iron, working transversely backwards and forwards across the sheet of glass, which is made to travel longitudinally from end to end beneath them. When the sheet has been polished on one side, it is turned over on the machine, and the other side polished in the same manner. The emery used in the smoothing process is sorted into the different degrees of fineness by a simple apparatus consisting of a series of vessels of different sizes, arranged in succession according to size, through which a current of water is made to pass, flowing through each with a velocity inversely proportioned to the size of the vessel. The emery to be sorted is fed into the stream of water entering the first or smallest vessel, in which the current is most rapid, and only the largest and heaviest grains of emery therefore are deposited in this vessel, the finer portions being carried along by the force of the current and deposited similarly in the second and succeeding vessels, according to their degrees of fineness. A series of specimens was exhibited of the glass from the several stages of the manufacture, and also of the emery and other materials employed in the different processes.

The meeting then terminated.

ON THE NUMERICAL EXPRESSION OF THE DESTRUCTIVE ENERGY IN THE EXPLOSIONS OF STEAM-BOILERS, AND ON ITS COMPARISON WITH THE DESTRUCTIVE ENERGY OF GUNPOWDER.

By George Biddell Airy, Astronomer Royal.

1. A little consideration of the changes in the state of the water and steam, which occur during the bursting of a steam boiler, will show that very little of the destructive effect of an explosion is due to the steam which is contained in the steam-chamber at the moment of the explosion. The rupture of the boiler is effected by the expansive power common at the moment to the steam and the water, both at a temperature higher than the boiling-point; but as soon as steam escapes, and thereby diminishes the compressive force upon the water, a new issue of steam takes place from the water, reducing its temperature; when this escapes, and further diminishes the compressive force, another issue of steam of lower elastic force from the water takes place, again reducing its temperature; and so on; till at length the temperature of the water is reduced to the atmospheric boiling-point, and the pressure of the steam (or rather the excess of steam-pressure over atmospheric pressure) is reduced to 0. It is the enormous quantity of steam, of gradually diminishing power, which is thus produced from water during the course of the explosion, that causes the disastrous effects of the explosion: compared with this quantity, the small volume of gas, which may happen to be in the steam-chamber at the time, is, in boilers of ordinary construction, wholly insignificant, and may be entirely put out of sight in the succeeding investigations.

2. If we compare the course of changes, in bursting, in two boilers, a large one and a small one, we see that the order of changes is the same in both; but that to reduce the temperature of a large body of water by a certain number of degrees a large volume of steam must escape, whereas, to reduce the temperature of a small body of water by the same number of degrees, it will suffice that a smaller volume of steam (smaller in the same proportion as the bulk of water) escape. Thus it will appear that the whole volume of escaping steam at a given pressure, and the whole destructive energy of the steam, are proportional to the bulk of water.

3. For measure of the destructive energy of the steam, we must suppose the simplest and most easily measurable case—namely, that the steam, in expanding, drives a piston along a uniform cylinder. It is necessary to ascertain the value of the pressure F when the steam has expanded so far as to have pushed the piston to the distance x: then the measure of the total energy is $\int dx \, . \, F$, the integral being taken from the point where the piston was in contact with the water to the point where the excess of pressure of the steam above atmospheric pressure $= 0$.

4. In the case of gunpowder fired in a cannon, where the weight of the ball and its velocity on emergence are found by experiment, the energy of the gunpowder as acting on the ball will be thus found:—The pressure at distance y being F', acting on a ball whose weight is W, and g being the numerical measure of the acceleration produced in one second of time by gravity ($g = 32{\cdot}1908$ if the unit of measure is the English foot, or $= 9{\cdot}8116$ if the unit is the French metre), v being the velocity at distance y, and V the whole velocity acquired, then the acceleration is $\frac{F'g}{W}$, and therefore $v\frac{dv}{dy} = \frac{F'g}{W}$, $v^2 = \frac{2g}{W}\int dy \, . \, F'$, and $V^2 =$ total integral $\frac{2g}{W}\int dy \, . \, F' = \frac{2g}{W} \times$ total energy, whence the total energy $= \frac{W \, . \, V^2}{2g}$. And if w be the weight of the gunpowder, the energy of one unit-weight of gunpowder $= \frac{W \, . \, V^2}{2g \, . \, w}$.

5. Several years ago (before 1849) I had desired in this way to compare the destructive energy of steam from a bursting boiler with that of gunpowder; and I had requested the assistance of my friend, Professor W. H. Miller, of Cambridge (to whose knowledge of the progress of accurate science in every department of physics I have often been indebted), to enable me to give numerical values to the expressions involved. At that epoch, however, the theories and experiments on steam were not sufficiently advanced, and I was compelled to lay aside the inquiry for a time.

6. In the spring of the present year I requested Messrs. Ransomes and Sims, of Ipswich, to furnish me with an experimental result on the quantity of water escaping from a high-pressure boiler in the form of steam when the valve is gradually opened. This experiment was undertaken by George A. Biddell, Esq., Engineering Superintendent of the Orwell Works. The result was that, when the bulk 22 cubic feet of water in a locomotive boiler was raised to the temperature which produced a pressure of 60 lbs. per square inch, and when after raking out the fire the valve was gradually opened without every precaution against priming, the quantity of water which escaped in the form of steam was 2¾ cubic feet, or one-eighth of the whole.

7. Possessed of this experimental fact, I again referred to Professor Miller for such theories and citations of experiments as might be required. And by his kind assistance I was enabled to com-

plete the investigation. And here I may state that the whole which follows is Professor Miller's, with the exception of the integration of the steam-pressures, the inference from the cannon-experiments, and the comparison of steam and gunpowder.

8. In giving the heads of Professor Miller's theory, I must premise that the temperatures are Centrigade, the unit of linear measure is the metre, and the unit of weight is the kilogramme. The formula adopted as connecting the volume of steam with the volume of water (at maximum density) from which it was generated, is Fairbairn's and Tate's (Phil. Trans. 1860, p. 219). The formula for the number of *calories* required to convert water into saturated steam of temperature T, and the pressure at temperature T, are from Regnault (*Memoires de l'Institut*, vol. xxi., pp. 748 and 728).

9. The first part of Professor Miller's investigation applies to Mr. Biddell's experiment. The steam-pressure of 60 lbs. per square inch is represented by a column of mercury (at 0 deg.) 3·1028 metres in height. Adding the atmospheric pressure 0·76 metre, the entire elastic force of the steam is represented by a column of mercury 3·8628 metres in height. The corresponding temperature of saturated steam, by Regnault's Table, is 152·84 deg. Now the quantity of water is 22 cubic feet, which at 100 deg. weigh 597·1 kilogs., and the heat requisite to raise the temperature of this water from 0 deg. to 152·84 deg. is 597·1 × 154·38 *calories* (the last number being derived from Regnault's formula $T + 0{\cdot}00002\ T^2 + 0{\cdot}0000003\ T^3$, where T for this instance = 152·84), or 92,182 *calories*. When all the steam has been blown off, the 597·1 kilogs. of water are separated into x kilogs. of steam at 100 degs., and $(597{\cdot}1 - x)$ kilogs. of water at 100 deg. [This applies strictly when the steam has blown into a cylinder and has driven a piston, because then there may be such intercommunication of temperature between the portions of steam as will ensure that the final state of the steam is that of saturated steam at 100 deg.; it is probably true or very approximate when the steam has blown out at different temperatures and has been lost in the atmosphere.] To heat $(597{\cdot}1 - x)$ kilogs. of water from 0 deg. to 100 deg. requires $(597{\cdot}1 - x) \times 100{\cdot}5$ *calories*; and to convert x kilogs. of water at 0 deg. into steam of 100 deg. requires $(606{\cdot}5 \times 0{\cdot}305 \times 100)$ $\times\ x$ *calories* (by a formula of Regnault's). Supposing, then, that the amount of heat as measured by the number of *calories* is not altered by the blowing out from the boiler,

$$92{,}182 = (597{\cdot}1 - x) \times 100{\cdot}5 + 637 \times x,$$

whence x, the weight blown out as steam, = 59·8. This, however, is equivalent to only 2·2 cubic feet of water, instead of 2·75, the quantity which Mr. Biddell found to have passed away in steam.

10. Professor Miller supposes the difference to be caused principally by the heat of the mass of iron which surrounds the water; any burning fuel which may have been left in the firebox would add slightly to its effect. It appears best, therefore, to assume the experimental fact, and to infer from it what quantity of heated water we ought to add (in investigations) to the quantity of water really present in the boiler, in order to produce correctly the amount of water which in the experiment was blown out as steam. Now 2·75 cubic feet of water at 100 deg. weigh 74·638 kilogs. Let y represent the number of kilogs. in the bulk of water which may be considered equivalent to the compound consisting of 22 cubic feet of water, the unknown weight of iron, and the unknown quantity of fuel. To heat y kilogs. of water from 0 deg. to 152·84 deg. requires $154{\cdot}38 \times y$ *calories*; and this is the amount of heat in the complex equivalent before blowing off. To heat $(y - 74{\cdot}638)$ kilogs. of water from 0 deg. to 100 deg. requires $(y - 74{\cdot}638) \times 100{\cdot}5$ *calories*; and to convert 74·638 kilogs. of water at 0 deg. into steam at 100 deg. requires $74{\cdot}638 \times 637$ *calories*; and the aggregate of this with the last, or $(y - 74{\cdot}638) \times 100{\cdot}5 + 74{\cdot}638 \times 637$, represents the number of *calories* in the complex equivalent after the blowing off. Making this equal to the number before blowing off,

$$154{\cdot}38 \times y = (y - 74{\cdot}638) \times 100{\cdot}5 + 74{\cdot}638 \times 637,$$

whence $y = 743{\cdot}2$.

Comparing this with the weight of the 22 cubic feet of water alone, or 597·1 kilogs., it appears that the heated materials extraneous to the water produce the effect of 146·1 kilogs. of water.

11. Assuming then that there are really 743·2 kilogs. of heated water, the investigation of the destructive energy proceeds thus:—To heat 743·2 kilogs. from 0 deg. to 152·84 deg. requires $743{\cdot}2 \times 154{\cdot}38$ *calories* = 114,740 *calories*; and this is the quantity of heat for which we must account in every stage of the expansion, when the steam is allowed to blow into a cylinder and drive a piston before it. Now at any instant let w be the number of kilogs. of water converted into saturated steam; T the common temperature of the water and steam; Q_T the number of *calories* required to heat 1 kilog. of water from 0 deg. to T; λ_T the number of *calories* required to convert 1 kilog. of water at 0 deg. into steam at T; P_T the pressure of saturated steam at T in millimetres of mercury at 0 deg.; K_T the same pressure in kilogrammes per square decimetre (all which are given for numerical values of T by Regnault); V_T the ratio of the volume of saturated steam under pressure P_T to the volume of the water at 0 deg. from which that steam is derived (which is given by Fairbairn's formula). Then, forming the expressions for the number of kilogs. of water and steam respectively, and multiplying each by its corresponding number of *calories*, and equating the aggregate to the original number of *calories*,

$$114{,}740 = (743{\cdot}2 - w) \times Q_T + w \times \lambda_T$$

From this formula, with any assigned numerical value of T, w (the number of kilogrammes of water converted into steam) is found in numbers. And V_T, the ratio of the volume of the steam generated to that of the water from which it is generated, is taken in numbers from Fairbairn's formula. And a kilogramme of water occupies one cubic decimetre of volume. Therefore the volume of steam, in cubic decimetres, is $w \times V_T$, of which w are left in the boiler to occupy the place of the expanded water; and the volume of steam expelled from the boiler is $w \times (V_T - 1)$ in cubic decimetres, or $\frac{w}{1000} \times (V_T - 1)$ in cubic metres.

12. Suppose, now, that the steam in escaping enters a cylinder whose section is 1 square metre, driving a piston before it. Let z be the distance to which the piston has travelled (the unit being the metre). Then $z = \frac{w}{1000} \times (V_T - 1)$. And the pressure of the steam on the piston (the unit being the kilogramme) is $100 \times K_T$. Therefore the two elements, the distance of the piston and the pressure upon it, can be calculated numerically for any number of numerical values of T. To find the effective pressure, the pressure first found must be diminished by the atmospheric pressure, or by the pressure of steam at 100 deg., and it thus becomes $100 \times (K_T - K_{100})$. The limit of the length of the cylinder will be determined by finding where the steam pressure = atmospheric pressure. By Fairbairn's formula, 74·638 kilogrammes of saturated steam at 100 deg. (the quantity which escaped in Mr. Biddell's experiment) occupy 122·28 cubic metres; of this, 0·0746 cubic metre remains in the boiler, taking the place of the water from which it was produced; the whole volume expelled is therefore 122·21 cubic metres, and the limiting length of the cylinder is 122·21 linear metres.

13. By these methods Professor Miller calculated the following corresponding values of z, the distance to which the piston has travelled (the unit being the metre), and F the effective pressure on the piston (the unit being the kilogramme). The degrees of temperature are also given, as they are the elements from which z and F are computed; but they are not in any way used in the subsequent calculations.

T. Degrees Centigrade.	z. Metres.	F. Kilogrammes.
152·84	0	42,185
150	1·621	38,356
145	4·743	32,162
140	9·315	26,615
135	14·740	21,663
130	21·541	17,271
125	30·136	13,377
120	40·976	9,943
115	54·708	6,926
110	72·186	4,288
105	94·325	1,991
100	122·21	0

14. The effective energy of the expanding steam, as shown (for instance) by the momentum communicated to a material piston, will be represented by the integral $\int dz \,.\, F$. As the symbolical form of the function F is not known, it is necessary to perform the integration by quadrature. For this purpose I laid down the twelve data of this Table graphically (taking z as the abscissa, and F as the ordinate), and drew a curve by hand through the points so defined. Then I measured the ordinate for each of the values of z; 0, 1, 2, 3, &c. And I integrated them by the formula ½ (first ordinate + last ordinate) + sum of intermediate ordinates — 1-12th sum of second differences; where it is seen that sum of second differences is sensibly equal to — first of first differences. Thus I found the integral

1,131,400,

which is the true measure of the energy of the 22 cubic feet of water at the temperature which produces the pressure 60 lbs. to the square inch, in a hot iron boiler, the units of the energy being the metre and the kilogramme.

15. If this be diminished in the ratio of 743·2 kilogrammes (the fictitious weight of water on which Professor Miller's calculations are made) to 597·1 kilogrammes (the real weight of water), then we shall have for the measure of the energy of the 22 cubic feet of water at the same temperature, unassisted by the hot iron of the boiler,

909,000;

and if we divide the two numbers by 22, we have for the energy of one cubic foot of water a temperature producing a pressure of 60 lbs. to the square inch,

As surrounded by hot iron, 51,400. (This is the practical value.)

Without influence from surrounding iron, 41,300 (This is the philosophical value.)

16. I now proceed with the evaluation of the energy of gunpowder. The formula applicable to cannon experiments is given in Art. 4. Professor Miller referred me to a series of experiments by General Didion, in his *Traite de Balistique*, p. 485. These experiments were made with cannon of four different bores, and with eighteen different charges of powder in each cannon. The first thing to be done was, to find by trial for each cannon, by means of the formula $\frac{W \,.\, V^2}{2g \,.\, w}$ (which for a single cannon may be reduced to $\frac{V^2}{w}$), what was the charge of powder in which the momentum produced bore the greatest proportion to the weight of the powder. It was found to be the following:—

With ball of 12 kilos.,	1·500 kilos. of powder.		
,, 8·07 ,,	1·250	,,	
,, 6·08 ,,	0·875	,,	
,, 4·05 ,,	0·625	,,	

Then adopting these four for comparison among themselves, by the formula $\frac{W \,.\, V^2}{w}$, it was found that the cannon in which the powder was most efficient was that with a ball of 6·08 kilogrammes. Here it may be desirable to state that the bore was 0·1213 metre, the diameter of the ball 0·1182 metre, the length of bore 2·815 metres; and, with the charge of powder 0·875 kilogramme, the velocity of the issuing ball was 400 metres per second. Applying the formula $\frac{W \times V^2}{19{\cdot}623 \times w}$, the energy of 1 kilogramme of gunpowder (as fired in a cannon) is found to be

56,656,

and that of an English pound of gunpowder

25,700,

the units being in all cases the metre and the kilogramme.

17. Comparing this with the numbers found in Art. 14, we have,

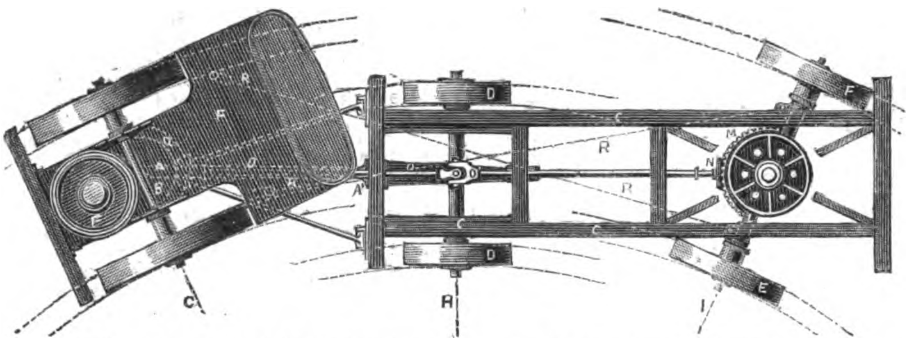
The destructive energy of 1 cubic foot of water at the temperature which produces the pressure 60 lbs. to the square inch, surrounded by hot iron, is precisely equal to the destructive energy of 2 lbs. of gunpowder as fired in a cannon.

18. The destructive energy of the hot water, however, abstracting the effect of the surrounding hot iron, is considerably less than the number used in this comparison; and the destructive energy of the gunpowder, abstracting the effects of windage, cold iron, and short barrel, is considerably greater than the number used for it. Without pretending to form an accurate estimate of these effects, I think that their combination, with that affecting the energy of the water, may have diminished the apparent proportion of the energy of gunpowder by one-half. In that case,

The destructive energy of 1 cubic foot of water at the temperature which produces the pressure of 60 lbs. to the square inch, is equal to that of 1 lb. of gunpowder.

The managing directors of the Thames Shipbuilding Company have formally announced to the Lords of the Admiralty that the "Minotaur" will be launched on the 12th December. The "Minotaur" is 6,621 tons, 1,350-horse power, and she will carry 38 heavy guns.

BARCLAY'S TRACTION ENGINE.



BARCLAY'S IMPROVEMENTS IN TRACTION ENGINES.

THIS invention, patented by Andrew Barclay, engineer, of Kilmarnock, relates, in the first place, to certain improvements in the construction and arrangement of traction engines, which improvements are based upon an invention, of a similar kind, patented the 10th day of March, 1862, No. 646.

Under one modification of the present invention, as applied to traction engines of the "right-angled class," the crank shaft of each pair of engines has its bearings at one end arranged in the side standard or frame, whilst the other end is connected to the main axle or to the centre of the driving wheel, so that this end of the shaft vibrates with the motion of the spring of the driving wheel whilst the other end remains a fixture in its bearing. The other pair of engines have their crank shaft arranged in like manner, the fixed bearings being on opposite sides of the machine. In this way the vibratory motion of the wheels as they traverse over the inequalities of the road, is imparted to one extremity of each crank shaft but without affecting the opposite ends, which revolve steadily in their bearings.

The object of the arrangement is to prevent the vibration of the driving wheels from affecting the beat of the valves. The driving wheels are arranged—one with a long tubular axle to which the wheel is keyed and extending across the framing; the other wheel is fitted with an axle which passes through the tubular one, and is fastened by a nut. Or the two axles may be arranged parallel to rotate in contact, and thus obtain an extended bearing surface when the engines are driven at different speeds. The traction engine is coupled to the vehicle accompanying it by a T-shaped connecting piece which is carried on a vertical spindle, its prolongation passing through two bushes carried by the framing of the connected carriages, the hind wheels of which are connected with the engine by means of a shaft and wheels, or by connecting rods direct, so as to angle along with the engine when going round a curve. This arrangement admits of the lateral and vertical movements of the coupled engine and vehicle. The traction engine may also be guided as well as regulated in speed by means of a duplex break action which is operated by a single hand lever so that the motion may be checked or the break applied to either side of the machine, and so guide it by the different speeds of the driving wheels. The improved pressure gauge consists of a metal or other chamber formed in two parts and divided by an elastic air-proof diaphragm. Above the chamber is fitted a graduated glass tube partly filled with water, which rests on the elastic diaphragm. The pressure of the steam raises the diaphragm and column of water, causing the air to be compressed, and in the ordinary gauges the air escapes through the water when subjected to long-continued pressure, but by interposing the diaphragm of elastic air-proof material this escape is prevented and the gauge continues correct in its indications.

The accompanying drawing, is an outline plan of a traction engine and frame of a truck carriage showing the necessary parts, as arranged in accordance with one modification of this invention, in relation to the coupling of traction engines with trucks or carriages.

The first part of his invention has reference to the aforesaid Letters Patent, and consists in arranging the crank shafts of these engines so that one end upon which a pinion is keyed vibrates with the motion of its supporting spring or springs, but so connected with the main axle of the driving wheels that both vibrate simultaneously in the same direction. This is accomplished by means of a rigid connecting link through which the crank and driving shafts pass. The crank shaft end of this link is fitted with brass bushes, and the crank shaft revolves freely therein; the other end of the crank shaft is supported in the side standards forming part of the main framing, and this end does not vibrate with the supporting spring's action, and in this case the throw of the valves is as regularly wrought by the eccentrics as if both ends of the shaft were stationary as regards the machine itself: the chief feature being the arrangement for allowing only one end of the engine crank shaft to vibrate and not the other.

Another part of this invention has also reference to the before-mentioned Letters Patent, and consists in the connecting of traction engines to their accompanying trucks or carriages, by a T-shaped swivel, coupling bar A, as shown partially in dotted lines in the accompanying drawing. The T-shaped coupling bar A is arranged between the engine and carriage; one modification of it is shown at P and F.

In this arrangement the centre of the shorter vertical arms of the bar A is coupled to the engine framing immediately underneath the centre of the main axle B, and its horizontal arm A^1 is connected with the accompanying carriage, in a manner somewhat similar to that previously described and shown in a previous patent, except that the part of the frame c to which it is attached is formed of iron and hinged to the axle K of the fore wheels D, so that the coupling bar swivels on three centres, on a vertical axis at A, on a horizontal longtitudinal one at A^1, and on a horizontal transverse one at K. The truck or carriage C is supported on four wheels in this modification; and instead of the fore pair of wheels D swivelling on the carriage, it is the rear pair of wheels E, on the axle L, which is made to swivel simultaneously with the traction engine F, shown in plan in the figure.

The fore axle K of the truck or carriage C maintains its position square across the carriage, and the direction of the dotted lines G, J, and I, J, with H, J, show that the angles of the three shafts meet in the centre J, upon which centre the engine turns. The rear axle L is pivoted between two snugs formed on the lower side of the bevel segment M, and this segment is in gear with a bevel pinion N, on the one end of the central shaft O, which shaft has also on its other end a similar pinion P in gear with a bevel segment Q, bolted to the lower side of the engine foot plate, so that any angle given to the engine by the steam steering handle is also imparted to the rear axle L of the truck or carriage, and the whole turns on the required curve without any slipping or slurring of the wheels, as each wheel is loose on its own axle. The shaft O is formed in two parts connected by a universal joint O^1 over the centre of the axle K, where the coupling bar A swivels to suit the inequalities or different levels of the roadway. Instead of the bevel gear just described being employed for actuating the rear axle L, two connecting rods R, R, shown in dotted lines, may be coupled direct between it and the axle B, or to the engine frame at a limited distance behind and parallel to the axle, which will serve a similar purpose, and turn the rear axle L simultaneously with the engine and so as to turn in the same arc. The shaft or shafts of the engine driving wheels may be constructed with an extended bearing surface by making one of these shafts hollow, and the other passing through that hollow shaft. The driving wheels A, A^1, are represented one in vertical section and the other in elevation. The hollow shaft B which is keyed into the nave of its driving wheel A, extends the whole breadth of the engine framing and within the hollow shaft B, the solid shaft C, which is made fast to the nave of its driving wheel A^1, revolves freely either in the backward or forward direction when going round a curve.

In another modification for extending the length of bearing in the driving wheel shafts, the axles B and C are placed parallel to each other at any convenient distance apart, or they may be arranged in almost close contact, the one driving wheel being to that extent in advance of the other, as shown. A novel steam pressure gauge is employed for registering the boiler pressure, which consists in the use of an elastic steam-tight diaphragm between the water contained in an air-tight glass tube and the steam, so that the enclosed air cannot escape down through the water and diaphragm. The contained water, being constant and non-elastic, rises up the small sealed tube from the enlarged space above the diaphragm by the pressure of the steam below it, so as to compress the contained air, and indicate the pressure of the steam by the varying level of the water in the tube, and graduated index divisions on its outside, in accordance with the first adjustment of the instrument.

THE LONDON ASSOCIATION OF FOREMEN ENGINEERS.

THE ordinary monthly meeting of the above society took place on Saturday, the 6th inst., at 35, St. Swithin's-lane, City. In the absence of the President, Mr. Newton—who, it was announced, was suffering from the effects of a rather serious accident—Mr. John Ives filled the chair, the vice-chair being occupied by Mr. Sanford. After the approval of the minutes of the preceding meeting, and the election and nomination of several new members, Mr. Oubridge proceeded to read a Paper on "A Method of Casting Guns Hollow, and Cooling them from the Inside by a Current of Air."

The reader remarked that the subject which he proposed to consider that evening was one upon which much had been already said and written. He believed, nevertheless, that it was not exhausted; for it was a fact that, as yet, no heavy gun had been produced which answered all requirements. Brass guns had had their day, cast-iron guns had been long used, were at one period almost totally condemned, but were now cropping up again, and much might be adduced in their favour. Wrought iron, in multifarious forms, had been employed in the manufacture of guns, each form having peculiar advantages; but the results, on the whole, were not satisfactory. Steel had also been introduced for the purpose; but, in spite of its great cohesive strength, it had been found impossible, hitherto, to make from it good, sound, and serviceable guns of large calibre. Many practical difficulties stood in the way of its employment in this direction, although certainly some very successful efforts had been made to construct light and small pieces of ordnance of that material. Compound guns, composed of cast and wrought iron—the one encasing the other—had also been tried, with variable and uncertain effects; but as yet no absolute rule had been deduced for the guidance of those whose duty it was to manufacture heavy guns. Time, and the expenditure of much more of the public money, might effect this vast desideratum; but it had not yet been achieved; and it was, therefore, the duty of practical and scientific men, to endeavour to solve the problem "how best to manufacture heavy guns?" He (Mr. Oubridge) intended to contribute a few items to the mass of

existing information on the subject, and he might state that such knowledge as he had to impart, had been gained from his own experience and experiments in the iron foundry. It was required in the production of large pieces of ordnance, that the material used should be made to offer the fullest possible resistance to the bursting strain to which it would eventually be exposed, and that the cohesive strength of that material should be completely maintained. Perhaps, before advancing his own views, he might be permitted to refer to the method of casting heavy guns, which had been largely practised during the unhappy contest which still raged in America. The name of Dahlgren would no doubt be familiar to his hearers in connection with the American civil war; and the guns which were known as "Dahlgrens," possessed some distinguishing features. They were cast hollow, the theory of their invention being that it was desirable "to reduce the neutral axes of his gun as nearly as possible to the centre of the thickness of the metal of which it was formed." This would be clearly seen to be the case from the diagram produced. If, on the contrary, the gun were cast solid, the cohesive power of the metal would be diminished as it approached the centre of the gun. By casting the gun hollow, this deteriorating process would be lessened by the pressure of the core in the mould. Dahlgren had evidently well considered the laws of cohesion and disintegration which governed these results. He had also adopted the plan of assisting the cooling and contracting by pouring a stream of cold air through a tube of iron inserted in the core barrel. In this way he was perfectly right, for it ought to be understood that if the cooling process operated entirely from the outer portion of the casting, it was, to use a familiar illustration, like casting an iron ring upon a mandril—an operation which they all knew would be a senseless proceeding. This plan had, however, been persistently followed until the Armstrong gun was introduced. He (Mr. Oubridge) had, several years before, submitted to the select committee of the Board of Ordnance a scheme for casting heavy guns hollow, but the reply of that body was, as usual in such cases, unsatisfactory. At the same period an American gentleman made some attempts to accomplish, in this country, the same thing, but without success. For his purpose six cupolas were erected near the Charlton Pier, on this side of the town of Woolwich, and the experiments there conducted were of a costly character. The theory was not the less a true one—the defeat lay in its imperfect realisation.

There was no doubt in his own mind that homogeneity would be obtained to a far higher degree in large iron castings if they were made hollow in place of being solid. He had had an opportunity a few months back, indeed, of practically demonstrating the fact. A large hydraulic cylinder, requiring 17 tons of metal to cast it, had to be produced. It was to have a very small hole through the bottom end, where the iron would be 15in. thick. He saw that the intense heat would inevitably melt the core barrel long before the metal composing the cylinder ceased to be fluid. He therefore assumed it to be a favourable opportunity for putting to the test his cherished theory. The casting was to be produced in the foundry of the Messrs. Simpson, at Pimlico; and Mr. Thompson, the manager for that firm, giving his consent, he determined to cool the core by means of an internal current of cold air. The plan of operation was very simple. A perforated tube was inserted in the core barrel, and then communicated by means of a pipe and valve, with the blast. As soon as the mould was filled with metal the valve was opened, and the cold air forced into the tube found an outlet through the perforations, whence it impinged upon the barrel. This latter was also perforated so as to allow of the escape of gases from the interior of the core. The result was a complete success, and the cylinder was as sound and homogeneous as could be desired. The cooling process had thus gone on from the centre, instead of the exterior of the casting. When he had considered that the operation had lasted sufficiently long to prevent the metal remaining in a fluid state, he caused the blast valve to be shut, and in half an hour the core barrel was found to have melted in one place, leaving an aperture 3 in. in diameter. The blast was then again turned on, and in less than ten minutes the barrel became black. By this method, which, as he said was of the most easy application, it was possible to reduce the temperature of the interior of a casting to almost any extent, and in a very short space of time. He desired to throw his mite into the treasury of human knowledge. It was for others to put it out, if they chose, to interest. Perhaps those who might be called upon to produce heavy castings, whether for the purposes of war, or in fulfilment of the more hallowed behests of peace, might be induced to take up the hints he had that night ventured to give. It was to be hoped that the practical founders of England, especially, would be permitted to exercise their own judgment as to the selection of the various irons best suited for heavy gun casting, and that in the manner of producing these castings they would not be hampered by mere theorising or "paper engineers," of whom too many had crept into the noble profession of which he was an humble member. He had a reverence for art and science, and for its practical exemplars, but not even ordinary respect for those who pretended to be its disciples, but were nothing more than pretenders. Mr. Oubridge's Paper was listened to with attention, and was well illustrated by diagrams. On its conclusion a discussion ensued, and this was followed by a vote of thanks. At 11 p.m. the members separated.

PREVENTION OF DECAY AND OXIDATION IN SHIPS.

As the prevention of decay in the timbers of wooden-built ships, and the fouling and oxidation of the plates of iron ships, have received considerable attention from the Admiralty and Merchant Shipowners, the following *resume* of all the specifications at the Patent-office bearing on this subject is given:—

Dipping timber in boiled oil is a very ancient practice, and it would be difficult to trace its origin. In 1739, Alexander Emerton took out the first recorded patent for preserving wood from decay. He prepared the planks or boards with boiling oil in the then old way, and afterwards coated them with compounded poisons, powdered glass and sand cemented with painting colours and oils, laid on as paint. The next patent, which was for preserving copper, or plates of which copper is a basis, was granted in 1790 to Collins and Wyatt. They covered the plates with lead or tin. In the early part of the present century several chemists recommended decoctions, in the form of vegetable poisons, for saturating timber, and thus destroying all animal life in the green wood. None of these poisonous solutions seem to have succeeded; for, had they been found efficacious, their application would have been continued. There was then an interval, during which the stoppage of decay seems to have been abandoned, and dry-rot allowed to take its course. In 1822, John Oxford secured a patent, whereby he undertook to prevent oxidation or decay in iron or wood, by preparing tar in such a manner as to stop the evaporation of the oil contained therein, saturating it also with chlorine gas. This purified oil is then mixed with 100 parts of white lead—or of the red oxide—25 parts of carbonate of lime, and 25 parts of purified coal tar added to the oil of tar. These ingredients are then applied as a paint. In the first days of iron in ship-building, rust was found to be a drawback to its general introduction. Scientific men saw the disadvantage, and sought to remedy the defect. Galvanic action, it was considered, would set all right, and the earliest patent in this direction was taken out by G. G. Bompass, in 1830. He sought to preserve metals from corrosion by an electric or galvanic process. For copper to be protected in sea-water he attaches an alloy of 9 to 10 parts of zinc with 100 parts of copper. In protecting iron he employed an alloy of tin, consisting of from 10 to 150 parts of tin combined with one of zinc. Following in the footsteps of Mr. Bompass, in the same year, Mr. John Revere patented an invention for fixing zinc protectors to the brass or stud of chain cables, and other iron surfaces exposed to the action of salt water. These galvanic zinc protectors were rivetted or soldered on according to requirement. It is known that one of the most distinguished of our electricians is in favour of inserting strips of zinc in the plates of ships; but if this principle proved correct in practice, it would long since have been universally adopted. Zinc plays an important part in patents for the prevention of oxidation. In 1837, Jacob Perkins got protection for a plan of coating copper tubes of boilers with a preparation consisting of two-thirds of zinc with one-third of copper; but he had been preceded in 1832 by Captain H. W. Craufurd, R.N., who proposed to preserve copper and iron from oxidation by coating with zinc paint in a fused state. Over this he laid a second covering of pure tin, or tin alloyed with lead. Captain Craufurd explains in detail his method of compounding the ingredients. In 1838, Le Comte de Fontainemoreau, considering Captain Craufurd's mode of fixing or adapting the zinc to this purpose as erroneous, applied for a patent of a more comprehensive description, for applying the zinc coating to metals. Again, in 1839, Mr. Thomas Dowling patented what he terms a conservative bath, applied to metals after grinding. He describes the machinery by which he effects this, the chief of which is a zinc wheel and galvanic vapour furnace.

In 1840, Mr. J. B. Neilson came forward with his invention for the application of a coating of copper, or copper alloyed with zinc or tin, or both, to the surface of iron. This was done by covering the mould to be cast with the material. In malleable iron, dried borax or flux is spread over the iron, which is then prepared with alloy heated to a temperature sufficient to melt copper, and, in its heated state, plunged into cold water to detach the scale of oxide. Mr. Arthur Wall, likewise in 1840, mixed 20 lbs. of the strongest muriatic acid diluted with three gallons of water, then added 12 lbs. of steel or wrought-iron filings. The filings were heated to redness before mixture. The whole was then subjected to heating in a pan, &c., and the composition was then applied to prevent corrosion. In 1841, Mr. W. E. Newton employed silicates of potash, or soda, for making a plaster or coating to prevent iron from becoming rusty. After him came Professor R. Mallet, engineer, of Dublin, whose varied processes are of the most complex character. Finding that iron covered with zinc, when immersed in sea water and certain fresh waters, gathered to itself a coating of carbonate of lime, destructive to the protective power of the zinc, and affording a surface for the attachment and growth of marine animals of the molluscous and testaceous classes, and aquatic plants, he applied chemical means to detach the scales of oxide from iron, and then plunged it into a preparing bath. After undergoing a series of processes, the metal is coated with an alloy or zoofagous paint, which paint is rendered poisonous by admixture of salts of metals, by means of which he sought to render the zinc effective as an anti-corrosive protector. In 1841, also, Mr. E. Morewood endeavoured to preserve iron from oxidation or rust by thinning it, and then dipping the tin covering or surface in molten zinc. Moses Poole, in 1845, claimed to possess an invention whereby he rendered iron more hard and durable, and free from oxidation, by the use of ferrocyanide of sodium, calcium, barium, or any other alkali, or alkaline earthy base; to be used in a manner fully set forth in his specification. In 1856, Mr. Andrew Smith improved upon the plans for melting the zinc. He employed a bath of lead or tin, or any composition or medium that melts at a lower degree of heat than zinc, by which means the heat from the fire of the furnace is taken up and transmitted to the receptacle containing the zinc for melting. Baron Wetterstedt, in 1846, added the regulus of antimony to lead sheets, combined copper with antimony, made sheet metal by using lead and tin, and lastly, protected metals by paints thus prepared:—1st. One part of regulus of antimony to three parts of copper, mixed, melted together, run out into water, and then heated gently. Two parts of oxide of copper are added, and moistened with naphtha. The whole is then added to a composition of tar and naphtha. 2nd. Another paint is compounded of 30 lbs. of tar, 80 lbs. of pitch, 20 lbs. of dried soot, 4 lbs. of tallow from sperm oil, and naphtha added for consistency.

Mr. C. H. Paris, in 1849, coated metals with glass or vitreous matter. The metal went through a cleansing process. Gum water is then applied, and over this the dry or powdered glass is shaken, and then fused by heat till a glass surface is formed. Mr. Paris claimed the application of carbonate of soda for applying glass in this manner. Mr. J. Macintosh, in 1852, made a paint from decomposed india rubber, in combination with oils or fatty matters saponified by metallic salts, with lime for thickening the liquid. For bottoms of ships he recommends the india rubber, when in a fluid state, to be combined with metallic soap, thickened with lime and coloured by pigments. Messrs. Hughes and Firmin, in 1852, manufactured lamp-black from the vapour of coal tar, dead oil, dead oil salts, coal pitch, naphtha, linseed oil, and other materials. From the products a fuel is produced, and this residue has by another inventor been mixed with oils, ground, and made into a paint. In 1852, also, Mr. R. M. Glover took out a patent for a preparation of arsenite of lead and arsenite of copper, and the red and yellow sulpharets of arsenic. The proportions of each were as follows:—Two parts, by weight, of arsenite of lead, one of realgar, one of orpiment, and one of arsenite of copper.

(To be concluded in our next.)

INGLIS' IMPROVEMENTS IN STEAM BOILERS AND ENGINES.

This invention, patented by Mr. W. Inglis, engineer, Edinburgh, relates partly to improvements in steam boilers, suitable more particularly, although not exclusively, for land engines, such improvements having for object reduced cost, facility for cleaning and repairs, and an efficient circulation of the water in a direction opposite to that of the fire gases, combined with a disposition of parts inducing the deposit of sediment where it can do comparatively little injury. It also comprises improvements in some of the details of land engines, although not exclusively confined to such engines.

In the accompanying drawings two modifications of the improved boiler are shown, figs. 1 and 3 being longitudinal vertical sections, and figs. 2 and 4, transverse vertical sections partially in end elevation.

In these modifications the principal heating surface consists of a series of comparatively long parallel tubes A with the water inside them, and fitted into end casings B, C, this combination being mounted in a position somewhat inclined from the horizontal. Excepting in the modification represented in figs. 3 and 4, the furnace D is placed beneath the higher portion of the tubes A, whilst the tubes are enclosed in a brick or other casing E in such a way as to cause the gases, after entering amongst them, to pass along them towards their lower ends. At the lower end of the tubes A the gases enter a flue F communicating directly with the chimney, but which may, if preferred, be made to pass first in contact with the other external parts of the boiler. The end casings B, C, are, by preference, arranged so as not to be directly exposed to the fire gases.

In the modification represented in figs. 3 and 4, the furnace D is placed above the inclined tubes A; and the fire gases, after passing along beneath the upper receiver H of the boiler, descend amongst the tubes A at their higher end, and then pass along them towards their lower end, and finally proceed along the flue F to the chimney, as in the other modifications. In this modification it is intended to introduce a forced air current under the grate. The steam generated in the inclined tubes A in the several modifications passes along them in the opposite direction to that of the fire gases, and enters from their higher ends into the higher end casing C, and thence, by one or more short tubes or connections G, into one or more upper receivers or vessels H, placed horizontally, or nearly so, above, and provided with the usual steam dome I. The upper receiver or receivers H communicate, by one or more tubes or connections J at the other end, with the lower end casing C below; and the result of these arrangements is that a very energetic circulation of the water takes place. The water-surface level is in the upper receiver or receivers H, and the steam, in rising into the same, carries water along with it towards the higher ends of the inclined tubes A into the higher end casing B, and into the receiver or receivers, whilst a corresponding amount of water returns downwards at the other end into the lower end casing C, and thence into the lower ends of the inclined tubes A. A strong current will consequently continually pass through the inclined tubes A, which are exposed to the fire gases and prevent deposits in them, the deposits, if any, taking place at the turn of the current in one or both end casings B, C, which casings are not directly exposed to the fire gases.

The improvements in steam engines are applicable to the gear for working steam admission valves, when (as in the "Corliss" engine) such valves are arranged to close by the action of weights or springs. One improvement consists in substituting rubber springs or spiral steel springs for the weights or blade steel springs hitherto used, the object being to avoid noise and liability to breakage. The application of this improvement is shown in the accompanying drawing. The admission valves of the steam cylinder A are actuated by rocking spindles B, having levers C on their ends. The lower ends of these levers C are actuated by rods D from the rocking disc or wrist plate E, which last is worked by the eccentric rod F, and which, by the rods G, also actuates the exhaust valve levers H. The upper ends of the admission valve levers C are linked to discs I, which work in the dash pots J, used in this class of valve to prevent concussion. The discs I are formed with spindles which work through the backs of the dash pots J, and are connected together by the rubber spring X, one spring thus serving for both valves. In fig. 6, a spiral steel spring Y is shown as applied in a similar way, excepting that it is connected to the same ends of the valve levers C as the rods D, as it reacts expansively, whilst the rubber spring X reacts by contracting.

In figs. 5 and 6, two modifications are shown of improved adjustable releasing gear. In that shown in fig. 5, each rod D has jointed to it a catch L, acted on by a spring, and arranged to lay hold of the block M, jointed on the pin of the valve lever C, and arranged to slide on the end of the rod D. The catch L has jointed to it a toe lever or bell crank N, which bears on the block M and lifts up and releases the catch at the proper time. The toe lever N is connected by a link P to a lever Q, adjustable by the governor rod R, or it may be by hand. It will

INGLIS' STEAM BOILERS AND ENGINES.

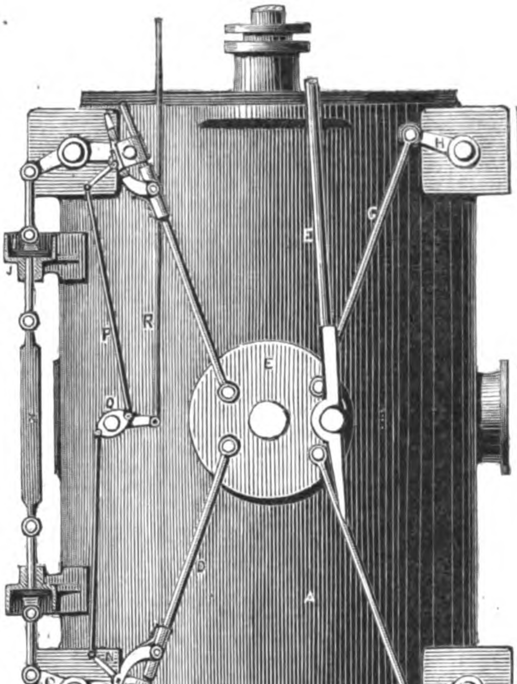

Fig. 6.

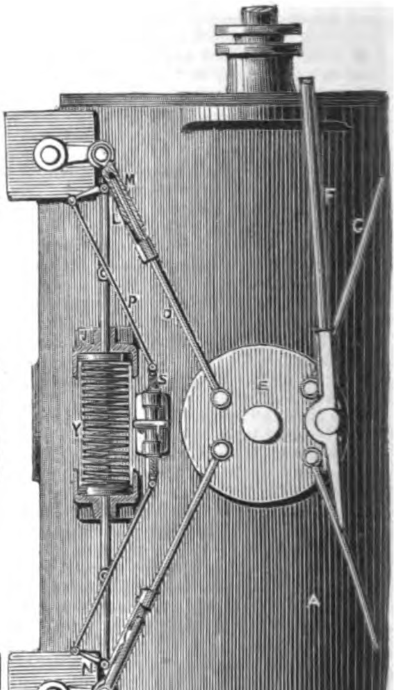
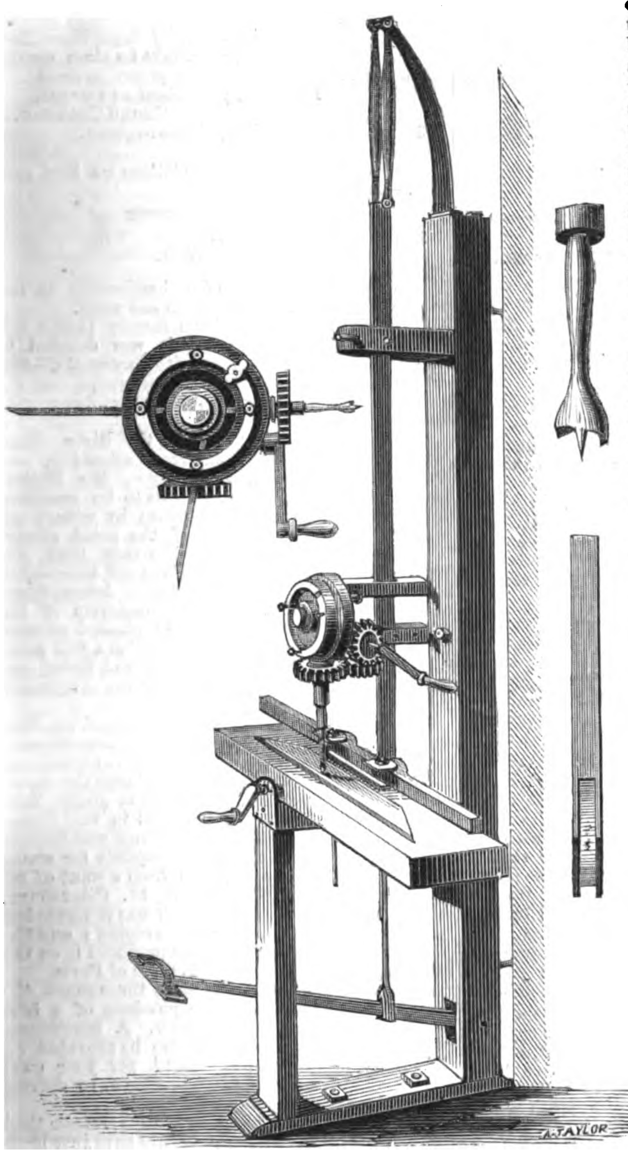


GERISH'S MORTISING AND DRILLING MACHINE.



be seen that the relative motions of the parts will cause the release to take place at an earlier or later period of the stroke, according to the adjustment of the lever Q, to which both links P are jointed. In the modification shown in fig. 6, the rod D is fitted to slide in a short rod M, jointed to the valve lever C, and is held in gear by a spring catch plate L, acted upon by a toe lever N, as in the other modification. The links P are jointed to spindles S, having right-handed and left-handed screw threads, and adjusted by means of a hand wheel T, internally screwed to correspond. When the adjustment is effected by means of the governor, a spring may be introduced to act in the opposite direction to the governor.

GERISH'S MORTISING AND DRILLING MACHINE.

Messrs. Gerish and Weston, of Shoe-lane, Holborn, have recently patented an improved machine for drilling and mortising wood, principally intended for manual labour, although it can be driven by power if required. When worked by a man, the motion is given by a treadle, where the whole weight of the body can be applied without any inconvenience, and the hands left at liberty. One end of a connecting rod is attached to the treadle, and the other to a vertical or upright bar, by which means this bar, on which the stock is fixed, moves up and down through two guides with comparatively very little friction; at the top end of this bar a couple of india-rubber springs are fixed, which bring the bar up at every stroke. The stock or tool holder, according to this invention, is made to slide up and down the bar and set at any required distance by means of a couple of set screws; it is made circular so that all the tools work from a centre; a pair of chisels are provided to each size, and eight sizes are supplied with each machine; these chisels are sure to follow in the same mortise when changed from right to left or *vice versa*, which is not the case where only one chisel is used. Very simple means are adopted to set the chisel on an incline to cut the wedging; a swivel is introduced in the back plate, which has an eccentric slot cut in it, and which is turned round by a knob or handle, into which slot a spring catch is made to fall; turning the swivel one way will set the chisel perpendicular, and the reverse way on an incline of 1 in 10 for wedging. Attached to the stock is a drilling apparatus suitable for wood or iron. The table is made to move backwards or forwards by means of an handle working a screw, and is made fast by a fly nut underneath. The fence is shifted up and down through the bed and is made fast by a couple of nuts. The chisel is a very ingenious contrivance for bringing the stuff out when cut; it will bring out two-thirds of the cut at each stroke, and the remainder will fall out, requiring no core-driver, and consequently effecting a very great saving of time and expense. The accompanying drawing illustrates the general appearance and details of the machine.

SYMONS' MARINE BAROMETER.

This barometer, patented by W. Symons, F.C.S., and shown and described at the recent meeting of the British Association, while equal both in accuracy and general appearance to the usual more expensive standard barometers, as Fortin's, &c., is superior to them in lightness, cheapness, and the ease with which an accurate reading may be taken, even by persons unaccustomed to such instruments. It is a modification of Gay Lussac's well-known syphon barometer, but is free from two objections to that instrument—viz., the want of a ready method of making it portable for carriage; and each limb of the syphon being read off by its own vernier, a calculation is required to get the final result. This is avoided in the new instrument, by dispensing with the bottom vernier and scale, and substituting an internal continuous metal tube, which is adjusted by a rack to the surface of the mercury in the short limb of the syphon. The scale and vernier are attached to the upper part of this internal tube, and read off in the usual way. In practice it is found much easier to adjust this instrument than, as is usual in most standards, to bring an ivory point just into contact with the mercury in the cistern. The barometer is rendered portable by a peculiar construction at the bottom of the short limb of the syphon, in which is inserted a steel wire carrying a piece of leather; this is moved up and down by a small knob, and a very small movement perfectly stops the flow of mercury.

A modification of this barometer for marine purposes was shown at the recent meeting of the British Association; and the inventor believes it is the first marine barometer with a full and accurate scale; the best now in use, having, of course, a scale contracted in proportion to the relative capacity of the tube and cistern. When the glass tube is broken, the instrument cannot be accurately repaired, unless the new tube be exactly the same size as the first. In the new instrument, no such absolute identity is required between the old and new tubes to ensure accuracy. At the same time the chance of breakage is less, not only from the lightness of the complete instrument, but Admiral Fitzroy has stated that the usual Board of Trade marine barometers have been broken by the vibration caused in firing a large gun; this, no doubt, has arisen from the necessity of fixing the glass tube firmly into the iron cistern. In the new instrument the tube may be entirely supported by elastic material without interfering with the accuracy of the instrument.

AN AMERICAN IRON-CLAD.

The iron-clad war-ship "Dictator," which is now being built at the large engineering establishment of Chas. Delamater, Esq., foot of Thirteenth-street, New York, from designs by Captain Ericsson, is based upon the principles of the first "Monitor," but will be different so far as relates to capacity, speed, sea-worthiness, and impenetrability to any armour vessel yet built in our country, or that is now being constructed, excepting its consort, the "Puritan." Some additional facts in relation to this vessel will be of general interest. The extreme length of the "Dictator," over all, is 314 ft.; its aft overhang being 31 ft., and forward overhang 13ft., leaving 260 ft. between perpendiculars; extreme breadth 50 ft., and depth 22½ ft. The hull, in sides and frame, is constructed of iron; the water lines are easy and the model good. The armour shelf extends outside of the hull 4 ft. on each side, and is prodigiously strong. An idea of its impenetrable character will be derived from the following account of its construction. The outside is covered with six one-inch plates of iron fastened in the most substantial manner, and inside of this are 3 ft. of oak timber and an armour lining formed of 4½-inch bars extending all around. The armour shelf, therefore, consists of 10½ in. in thickness of iron and 3 ft. of timber; and between the metal and timber is interspersed a thick layer of felting. No gun yet fabricated can project a shot that will pierce this armour jacket.

The keel plate of the "Dictator" is of 1-in. plate the side plates ⅞ in., and the frame of double angle-iron, 6 by 4 in. The interior is divided into several water-tight compartments by plate bulkheads, and the space forward of the third bulkhead below will be used for coal bunkers, through the middle of which will be a railway to carry the fuel to the boilers. The deck beams are of kyanized oak, and all the materials employed in the construction of this great war-ship appear to be of the best quality.

Two engines, each having a cylinder of 100 in. in diameter and 4 ft. stroke, will be employed to drive the screw, which is four-bladed, 21½ ft. in diameter and of 34 ft. pitch. Steam will be supplied from six large boilers capable of furnishing 5,000-horse power to the engines, and it is reasonably expected that the "Dictator" will have a high speed. As it is to be furnished with a strong iron bow, its speed, strength, and mass will render it a most efficient steam ram. It is to be provided which one revolving turret for carrying two of the most formidable guns with which it can be furnished; and it will be as impenetrable to shot of the most powerful guns as the solid rock of Gibraltar. The inside diameter of the turret will be 24 ft in the clear; a turret directly enclosing this will be formed of six thicknesses of inch plate, rivetted together; and over and outside of this will be another turret, forming a sleeve, consisting of seven thicknesses of inch plates rivetted together, and between these two circular shields, solid hoops or bars, 5 in. in thickness, will be packed and fastened securely; the whole forming one great revolving iron tower 18 in. in thickness, 27 ft. in diameter, and weighing about 200 tons. The design of the "Dictator," the care bestowed

upon its construction, and the excellent workmanship displayed upon every part of the hull and machinery, will render this vessel a credit and a powerful defence to our country. Every effort is being made to advance the work as rapidly as possible, and the launch may be expected in about three weeks or a month from the present date.—*Scientific American.*

GOVERNMENT EXPERIMENTS ON STEAM COAL.

It has long been a keenly contested question between the Northcountry and Welsh colliery proprietors as to which of the two classes of coal was best adapted for generating steam, and several experiments have been made by Government authorities without any definite result being arrived at. In consequence of the repeated applications made by the Northcountry proprietors, a series of experiments, extending over five weeks, have just concluded at the Devonport dockyard. The Admiralty were induced to make these experiments in consequence of the assertion of the Northcountry owners that a judicious mixture of the Northcountry or Hartley coal with the South Wales steam coal was far superior for the purposes of steam coal than either taken separately. The South Wales proprietors, feeling the importance of the issue, appointed Mr. Tomlinson, locomotive engineer to the Taff Vale Railway, as their representative. The *Times* states that, although several weeks must elapse before the official report is printed, it may be affirmed that the results will show that in no way has the superiority of the Welsh coal been affected; but, on the contrary, none of the mixtures experimented upon came up to the generating powers of the Welsh coal taken alone. This must be a gratifying result to the South Wales owners, who, in addition to the Navy, have been supplying for some time past large private steamship companies—such as the Royal Mail, Peninsular and Oriental, and Cunard lines, which fact may be taken as presumptive evidence of the superiority of the Welsh coal, as these companies have every inducement to purchase the best article in the market. It is probable that when the official report of these trials is published the question of Welsh *v.* Northcountry steam coal will be permanently settled.

Meetings for the Week.

Mon.—*Medical Soc.*, "Clinical Discussion," at 8.30 p.m. *British Architects*, at 8 p.m.

Tues.—*Inst. Civil Engineers*, 1, "Discussion on Red Sea Lighthouses." 2, "On the Duty of the Cornish Pumping Engines," by W. Morehead, jun., at 8 p.m.

Wed.—*Geological Soc.*, 1, "On the Fossil Corals of the West Indies." Part II. By P. Martin Duncan, M.B. 2, "On some Miocene Mollusca from Mount Séla in the Island of Java," by H. M. Jenkins, Esq., F.G.S. With a Note on a new Coral from the same locality; by P. Martin Duncan, F.G.S. 3, "Notes on the Geology of Japan," by Captain Bullock. Communicated by Sir R. I. Murchison, K.C.B., at 8 p.m.

Thur.—*Antiquaries*, at 8 p.m. *Linnean*, at 8 p.m.

Fri.—*Architectural Assoc.*, Class of Design—Single Bay of Large Church.

TO CORRESPONDENTS.

The Mechanics' Magazine is sent post-free to subscribers of £1 1s. 8d. yearly, or 10s. 10d. half-yearly, payable in advance. Post-office orders made payable to Mr R. A. Brooman, of 166, Fleet-street, E.C.

Advertisements are inserted in the Mechanics' Magazine at the rate of 6d. per line, or 5½d. per line for 6 insertions, 5d. per line for 13 insertions, 4½d. for 26 insertions, and 4d. a line for 52 insertions. Each line consists of about 10 words. Woodcuts are charged at the same rate as type. Special arrangements made for large advertisements.

All communications should be addressed to the Editor, 166, Fleet-street.

To insure insertion in the following number, advertisements should reach the office not later than 5 o'clock on Thursday evening.

T. F. (Newcastle).—We are quite in the dark, both as to the horse-power developed, and the coal consumed per hour, by steam fire engines.

T. Y. (Edinburgh).—An article appeared some weeks ago on boiler incrustation, in the Mechanics' Magazine, to which we must refer you. Easton's boiler fluid has been used with great success on the Great Eastern Railway, and in many other places.

Civilian.—This controversy is becoming too speculative and personal for our columns. We recollect an instance where a similar discussion was carried on for weeks in the pages of a contemporary without leading to any useful result; we therefore cannot think the insertion of any further letters on the subject advisable.

Paper Drapery.—Apply to Mr. Arthur Grainger, 308, High Holborn, W.C.

Correspondence.

SOCIETY OF ENGINEERS.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

Sir,—You remark, in your leader on the above Society, in your valuable journal of the 6th inst., that you "deem it best not to publish" the discussion that occurred there on the 2nd inst., hinting that "personalities" are out of place "in scientific discussion."

Now, I will ask you if you ever attended the meetings of the Institution of Civil Engineers, and if you ever heard much else than personalities at that place? At our Society, we have no inducement to refrain from speaking what we know, and no fear of offending this party or that; neither do we hesitate to say what we know, because Mr. This, That, or the Other does not hold the same views as ourselves; therefore it seems to me that you err in considering the remarks made by the various speakers as "personal."

The Society does not publish in scientific journals the discussions that take place at its meetings, only the Papers; and possibly the truthful way in which matters are stated by those present might be considered "personal" if it did so; but an abstract of each discussion appears in the "Transactions," published by Spon.

You remark that the use of gas in the furnaces of the steam fire-engine, at Watling-street, is beneficial as to getting steam quickly. This is not the case in practice; for I can refer you to cases where those engines have come to a fire with but 20 lbs. of steam, whilst other engines have started with cold water, and only lighted their fire on receiving the call, and arrived with steam of 100 lbs. on the inch, and got to work some time before the gas-fired engines could do so, and, as far as I can learn and observe, there is no benefit in practice obtained by its use.

I perfectly agree with you that a governor, or some equivalent, is necessary for the steam fire-engines with crank motion. This is proved by their continually breaking down; in fact, out of five fires attended by these engines, there have been serious breaks down at two—to say nothing of their requiring the free use of a pinch bar to help them along. My own observation convinces me of the superiority of a slow, steady, long stroke, as we find greater results produced in practice with less wear and tear, and no breaks down.

Yours, &c.,

A Member of the Society of Engineers.

London, November 7, 1863.

[We regret that our correspondent's note conveys the, we trust erroneous, impression, that the distinguishing feature of the discussions carried on by the Society of Engineers is personality. Far from denying the charge, he sets up the example (?) of the Institution of Civil Engineers as a justification, and goes on to state that we are in error in considering the remarks made as being personal; we prefer that we should be deemed so, rather than justify ourselves at the expense of a Society which has our best wishes for its prosperity. We shall be glad to see the statements contained in the latter part of the foregoing letter rationally discussed by our correspondents.—Ed. M.M.]

COLBURN *v.* CLARK.

Sir,—Even in finally abandoning his attempt to appropriate my ideas as his own, Mr. Clark cannot refrain from making rash and untruthful statements. To his unwilling admission that he had consulted my writings in preparing his contribution to the *Encyclopædia*, Mr. Clark adds the statement that his former assistant is in my employment. This is untrue; but were Mr. Dredge really in my service, I cannot see why, as a gentleman, his word should be the less worthy of credit on that account. If by "peculiar language," Mr. Clark refers to the curse which disgraced one of his former letters to me, I may remind him that he showed that letter to at least one person before sending it to me, and that when I showed it also to the same person (as I did to several others), he recognized the offensive expression at once. All this, however, has little to do with Mr. Clark's statement to you of September 25th last, and which, I think, must take its place among the boldest attempts at literary piracy on record.

I am, Sir, your obedient servant,

Zerah Colburn.

3, Upper Bedford-place, Russell-square.
November 11, 1863.

[We cannot insert any more letters on this subject.—Ed. M. M.]

Miscellanea.

The foundation stone of a breakwater at the mouth of the river Tees was laid last week.

At a recent meeting of the Mersey Docks and Harbour Board (Liverpool), it was decided to apply to Parliament for powers to borrow £875,000 for the construction of new dock works, on the Liverpool side of the Mersey, principally intended for the steam trade.

The cultivation of cotton in the River Plate territories is attracting universal attention, and the testimony of Mr. Hutchinson, the British Consul at Rosario, is conclusive as to its practicability and the vast regions which by nature are adapted for the production of the great staple. The Buenos Ayres *Standard* states that the Governor of Corrientes had received and distributed a ton and a half of seeds of different descriptions, and, after remarking that the majority of the estancieros of that province had planted or were about to plant cotton, predicts that "in a few years cotton will take the place of wool and hides, and become the first staple article of the Argentine Republic."

The Emperor's speech on the opening of the Session consisted of 2,044 words. The transmission by telegraph from the central station in Paris commenced as soon as it was ascertained that the reading had been completed, which was at about half-past 1. The average time occupied in the transmission to the principal cities of France and Europe was an hour and a quarter. The capitals for which the longest time was required from a want of direct communication were Rome, St. Petersburg, Athens, and Lisbon. The speech was nevertheless received everywhere before the evening; and the journals of the whole of Europe produced it on the following morning, the same as those of Paris.

The Ancient Order of Foresters throughout the country are contemplating the purchase of a lifeboat in connection with the Order. A boathouse, with all its requirements, will also be provided by the society, and it is stated that 1d. per year subscribed by each member will be sufficient to defray the expenses of maintaining it.

We learn from the *Army and Navy Gazette* that experiments of an important nature have just been made at the fortress of Carlberg, in Sweden, upon the respective merits of armour-plates made in England, France, and Sweden. Messrs. John Brown and Co., of Sheffield, sent two plates, one 12 ft. by 2 ft. 6 in., and one 6 ft. by 3 ft. 8 in. Messrs. Petin, Gaudet, and Co., of Lyons, sent two plates, each of 7 ft. 6 in. by 3 ft. 3 in. The Montala Ironworks Company, of Sweden, sent two plates of 12 ft. by 2 ft. 6 in., and one 6 ft. by 3 ft. 8 in. All the plates were of 4½ in. thickness, and then bolted to a teak target backed with iron plating, and supported by a massive stone pier. The two upper plates in the target were the French, and each was secured by 11 bolts. The next plate below was the longest, Swedish, and this was secured by 29 bolts. Below this was a tier of two short plates, one Swedish and one English, each secured by 24 bolts, and the lowest place was a long English, secured, like the Swedish, by 29 bolts. Each plate received six shots from the ordinary 68-pounder naval gun. The French and Swedish plates broke to pieces, and the English plates remained uninjured and free from cracks. The shot used were of Swedish iron, and exhibited great toughness as compared with shot used in the English service—the core or centre of the shot, after striking, being of double the weight of the core of the English shot.

A number of rolled armour-plates of a new description have been received at Chatham Dockyard, supplied by Messrs. Chapman and Co. The new plates, specimens of which have been tested in the usual manner to ascertain their condition, are intended for the stern portion of the "Achilles." Already there are four kinds of plates on the exterior of the "Achilles," supplied by as many different firms. The broadside plates were manufactured at the Parkgate Ironworks, by Messrs.

Beale and Co.; those on the port and starboard bows, where they are required to be tapered to suit the form of the vessel, by Messrs. Brown and Co., of Sheffield; and a few of the plates manufactured for the Government by the Thames Ironworks Company have likewise been used as required. The only part of the "Achilles" which is not yet encased in armour is the stern, on which about twenty more plates are required to be fixed to complete the work. Owing, however, to the difficulty attending this operation, from the peculiar rounded shape of the stern, the work of plating this portion of the vessel will occupy a much greater time. The date fixed for launching, or rather undocking, the "Achilles" is the 26th of December.

The want of hands in the agricultural districts of France has caused a demand for light steam ploughs to supply the defficiency. Twelve of these ploughs have been ordered for the Imperial farms. They are of two to five-horse power, and cost from 2,000f. to 6,000f. They are fixed on four wheels, and are light enough to be removed from one field to another by a pair of horses.

At the last sitting of the French Academy of Sciences, a new apparatus for enabling persons to remain under water, or in places filled with deleterious gases, was described. The apparatus consists of a piece of wood having the form and dimensions of the human mouth when open. To this piece of wood two india-rubber tubes are fixed, of any length, according to the exigencies of the case. The man engaged in the operation is further provided with a nose pincher, or instrument for compressing the nostrils, so as to prevent the introduction of the deleterious gas or of water, as the case may be. The operator puts the piece of wood into his mouth, and puts on the nose pincher; he stops up one of the orifices with his tongue, and inhales pure air from the other; after which he shifts his tongue to the latter orifice, and exhales his breath through the other. He continues thus regularly shifting his tongue from one orifice to the other in the order of the inspirations and expirations; but even a mistake would be of little consequence.

The Royal factories at Woolwich have commenced manufacturing guns of the new kind ordered by the War Department. A number of the old hands, discharged some time ago, have been re-engaged, and the work is ordered to be carried on night and day to ensure despatch.

The turning up of a horseshoe, real iron, from a depth of seven metres in the diluvium of pre-Adamite deposit bids fair to put out of joint the famous Abbeville jawbone. The phenomenon has been found on railway excavation in the Orne Valley, between Caen and Condé. The *Journal du Calvados* gives ample details, adding that not only horse bones and sundry other antediluvian fauna, but skeletons of the Hudson's Bay beaver are plainly recognizable.

The great demand for Welsh coal which is at present experienced at the port of Cardiff, where some hundreds of vessels are at the present time waiting their "stem," has called some attention to its cause, and it has been found from the daily clearances at the Bill of Entry Office that an immense quantity is being cleared for Nassau and contiguous ports. The advantages of a smokeless coal have been quickly discovered by the Confederates and their friends, who, in order to run the blockade, have found it necessary to employ the fastest steamers instead of sailing vessels. It is well-known that Cardiff has supplied a considerable quantity of the coal consumed on board several of the notorious Confederate privateers, and there can be no doubt that a coal devoid of smoke being a great *desideratum*, the Welsh coal has been found the most suitable. From 30,000 tons to 40,000 tons of steam coal are now being shipped from the port of Cardiff monthly.

A very interesting trial trip of the jointed steamer "Connector" took place on Saturday, on which occasion Mr. Reed, Chief Constructor of the Navy; Admiral Belcher; Captain Symonds, R.N., and other nautical gentlemen, were present. The "Connector" started from Greenwich during the height of the gale on that day, and, notwithstanding the severity of the weather, proceeded with her distinguished party down the river, eliciting the admiration of all at the excellent manner she behaved in the gale. When in the neighbourhood of Gravesend she disconnected and reconnected her sections, notwithstanding the roughness of the water, with perfect success, and ultimately detached her steam portion, with the Chief Constructor of the Navy and naval officers of the party, and landed them at Purfleet. She then reconnected and steamed against the full force of the gale back to London.

Patents for Inventions.

ABRIDGED SPECIFICATIONS OF PATENTS.

THE Abridged Specifications of Patents given below are classified, according to the subjects to which the respective inventions refer, in the following Table. By the system of classification adopted, the numerical and chronological order of the specifications is preserved, and combined with all the advantages of a division into classes. It should be understood that these abridgements are prepared exclusively for this Magazine from official copies supplied by the Government, and are therefore the property of the Proprietors of this Magazine. Other Papers are hereby warned not to produce them without an acknowledgement:—

---

834. G. S. GRIMSHAW. *Improvements in carding engines* Dated April 1, 1863.

In carrying out this invention, the inventor gives the roller, technically called the "licker-in," a differential speed, so that it will travel a greater space in a given time than the cylinder, by which he gains an economy in time by producing an increase of work more than can be done by the ordinary method, and also an improved quality. The proportion of the speed of the licker-in is about five and a third to one revolution of the cylinder. *Patent abandoned.*

835. J. HINDLE, W. F. CALVERT, and E. THORNTON. *Improvements in looms for weaving.* Dated April 1, 1863.

This invention relates to that portion of looms called the connecting rods or crank arms used for communicating motion from the crank shaft to the lay stay or batten, and consists in making each of the aforesaid rods or arms with an intermediate joint between the two joints connecting it with the crank and lay. The said intermediate joints are formed with partly squared ends or stops for holding the rods or arms perfectly rigid during the time the weft is being beaten up, but allow the joints to be turned when the crank has passed the centre for the return stroke, and thereby cause the arms to be thrown out of a straight line, and, consequently, shorten them to the extent of the angle that one portion bears to the other, thus bringing the lay back from the front to the bottom centre much quicker, and from the bottom to the back centre much slower than by the ordinary method, and allowing the picking motion to be brought into action considerably sooner than heretofore, and giving more time for the shuttle to pass and to a great extent easing the pick. 2, The improvements consist in causing levers, put in motion by the stop rod, to come in contact with a bracket on the crank arm, causing them to be thrown into an angular position, so as to allow the cranks to proceed without continuing the forward motion of the lay, and thereby avoiding the concussion and consequent wear and tear common to the ordinary loom, and also preventing the breakage of the yarn by the shuttle being caught or trapped in the shed. When the shuttle has to be delivered, the levers are pressed by the projections on the crank arms, and push back the swell fingers, and thereby relieve the shuttle in the box previous to the commencement of the pick, and they remain in the same position until the shuttle is boxed on the opposite side. *Patent completed.*

836. J. ROWLAND. *An improved mileage apparatus for measuring and registering the distances public vehicles or private carriages travel.* Dated April 1, 1863.

This invention is not described apart from the drawings. *Patent completed.*

837. J. BRAY. *Improvements in the construction of omnibuses, railway carriages, and other vehicles.* Dated April 1, 1863.

This invention is not described apart from the drawings. *Patent completed.*

838. M. HENRY. *An improved method of lubricating.* (A communication.) Dated April 1, 1863.

The patentee claims the employment or application of a cradle or frame, on or over which are carried or suspended cotton wicks, or other capillary conductors, in such manner that such wicks or conductors shall convey lubricating material from the reservoir or part containing it to the journal or other appliance or surface to be lubricated, as described. *Patent completed.*

839. W. CLARK. *Improvements in preventing fermentation in alcoholic and other liquids while drawing them from their containing vessels, and an apparatus for the same.* (A communication.) Dated April 1, 1863.

According to this invention, an apparatus is applied to the barrel or receiver communicating on the one hand with the receiver, and on the other with the external air. The apparatus contains a disoxygenating solution, arranged in such manner that the atmospheric air cannot enter the barrel without passing through the said solution, and giving up its oxygen thereto. In this manner, in place of the liquid drawn off at each time, there will be introduced an equal volume of azote, and although the azote may be in contact with a fermentable liquid, it will be incapable of fermentation when free from oxygen, as it is well known that oxygen gas is an essential element of fermentation. The disoxygenating solutions the patentee ordinarily employs consist of sulphate of lime and sulphite of protoxide of iron, either together or separately, and dissolved in water. *Patent completed.*

840. W. WEST. *Improvements in working railway signals.* Dated April 1, 1863.

This invention relates to the working of railway signals at a distance, and consists in the employment of a novel arrangement of self-adjusting apparatus, by means of which the expansion or contraction of the wire used for transmitting motion to the semaphore or other signal is compensated for, and the complete and rapid action of the signal ensured. In carrying out the invention, the patentee winds that part of the wire, chain, or cord nearest to the pull-over lever round a grooved wheel, and attaches it to the wheel at any given spot, carrying over the end of the wire, and suspending a weight from its extremity. The grooved wheel is free to move on its own axis, so that the weight will always keep a tension on the wire, chain, or cord. In order to work the signal, he rocks the wheel by means of the pull-over lever, which is provided with a self-acting clutch, so arranged as to grip the wheel when the lever is set in action, and rock the wheel, thereby putting such tension on the wire or chain as will ensure the change of the distant signal. *Patent completed.*

841. W. MITCHELL. *An improved process for coating iron.* (A communication.) Dated April 1, 1863.

This invention relates to a novel mode of coating articles of iron with protecting or lustrous metals, such as copper, gold, silver, nickel, zinc, tin, antimony, and bismuth, and their alloys. In depositing a layer of copper or a metallic alloy upon the surface of iron, the iron should be the best charcoal bloom, sound and free from blister, and of uniform temper. For making bronze iron for spikes, bars, braces, bands, or other appliances for ship-building, the iron should be good common sound iron. In preparing the iron for being rolled into sheets, care must be taken to obtain a surface free from indentation, caused by scales of oxide being forced into the plates of iron in the process of rolling. The oxide scale should be removed in time, so as to obtain a smooth surface similar to what is required for receiving a coat of tin. For more particular work, the iron should be rolled both ways to produce a cross fibre. The size of the plates when bronzed should always correspond to the size required when finishing, keeping in view the increase in length by rolling. For all other purposes the iron to receive the coat of metal should be prepared in the form and size required for use. *Patent completed.*

842. G. T. BOUSFIELD. *Improvements in steam boilers.* (A communication.) Dated April 1, 1863.

This invention consists in combining tubes through which the water passes, and which are in the furnace, with tubes through which the products of combustion pass, and which are surrounded with steam, or with steam and water, so that after the heat of combustion has partly spent itself in evaporating the water which passes through the water tubes, it will superheat or dry the saturated steam which is evolved from the water tubes, thereby commanding the highest evaporating power in the smallest compass, and with the greatest facilities for cleaning and repair. *Patent completed.*

843. E. B. WILSON. *Improvements in the manufacture of iron and steel, and other metals, and in the apparatus employed therein.* Dated April 1, 1863.

This invention consists in blowing into the cupola or melting furnace hydrogen gas, or a mixture of hydrogen gas with carbonic acid gas, obtained in any convenient manner, in conjunction with atmospheric air. The method adopted for the generation of the hydrogen and carbonic acid gases is to direct a blast of atmospherical r in conjunction with superheated steam through a separ at cupola or furnace containing fuel in a state of incandescence. From this cupola or furnace the gases so obtained, mixed with a certain amount of air so as to procure either a perfect or an imperfect combustion of the gases as desired, pass into the cupola or melting furnace, which is charged with the metal or ores to be reduced. The combined blast may be continued until the metal is refined. *Patent abandoned.*

844. A. GAVIN. *Improvements in the preservation of perishable liquids during the withdrawal or consumption thereof.* Dated April 1, 1863.

In the case of a cask or barrel being the holding receptacle of the liquid, the interior of such cask or barrel is made, according to the present invention, perfectly cylindrical. This cylinder is fitted with an accurately but loosely fitting disc, float, or diaphragm of wood or other material. When the cask is full of liquid, the disc or diaphragm floats or rests upon the surface of the contained liquid immediately beneath the cask head, and as the liquid is gradually withdrawn in the ordinary manner, the disc sinks with the descending level of the liquid. In this way, the liquid is kept entirely or nearly free from contact with the external atmosphere, as the cask is vertically kept always full of liquid. *Patent abandoned.*

845. W. H. PHILLIPS. *Improvements in means or apparatus for cleaning the bottoms of ships or other floating vessels.* Dated April 2, 1863.

For the purposes of this invention, the form of apparatus which the patentee prefers to employ consists of a circular frame or disc revolving freely upon a central axis, carried by a suitable framing or support, capable of being suspended from the deck (by one or more ropes or chains passing

around or underneath the vessel) and pressed against the bottom or side of the vessel to be cleaned when required. This framing may also be guided or stayed by chains or ropes passing fore and aft from it to either end of the ship, which chains or ropes may be used to give the brush a fore-and-aft movement, if desired, when in use. The surface of the frame or disc, which is thus pressed up against the bottom or side of the vessel, is of a brush-like character, composed of cane, whalebone, wire, or other elastic or yeilding materials, combined or otherwise with blades or rigid projections if desired. To the outer surface of the frame or disc is attached a self-acting revolving apparatus; but he prefers to use a series of vanes or blades which revolve as the vessel is propelled through the water, and which cause the apparatus mounted upon the axis to revolve by being connected to them by suitable gearing as the vessel so passes through the water; or they may be caused to rotate by the action of the tide when the vessel is stationary. The apparatus is capable of being shifted from one position to another by a crab, capstan, winch, or other means acting on the chains or ropes which support or suspend the apparatus. In place of attaching the brush or rubbing surface to the rotating disc by gearing, as above described, it may be separate therefrom, and have an oscillating or to-and-fro movement imparted thereto by means of a crank or other gearing connecting the revolving disc and the brush or cleaning instrument together; by this means a chipping or chopping-off action may be given to the cleaning instrument. When the vessel is in still water, motion may be communicated to the revolving brush or cleaning instrument by means of a driving band passing over a drum or pulley on the axis of the series of vanes or blades actuating the revolving disc to another drum or pulley mounted upon and driven from the deck of the vessel, or from a raft, barge, or other floating body lying alongside the vessel. The rotating brush or cleaning surface may be formed around the circumference of a drum having a central axis, to which rotary motion may be given by similar means to those previously described. *Patent completed.*

846. J. W. LAW and J. INGLIS. *Improvements in making moulds for casting, and in apparatus connected therewith.* Dated April 2, 1863.

This invention is not described apart from the drawings. *Patent completed.*

847. E. F. CLARKE. *Improvements in the means of fastening rails for railways.* Dated April 2, 1863.

This invention relates to the construction of the chairs and keys employed to support and fasten the rails to the sleepers on railways, and also to the method of fixing and securing the same. The chair is formed with a vertical slot tapering downwards, and which is cut or formed in the inner faces of the chair, and extends through the bottom of the same. The keys are each formed with a head which fits on the side of the rail, and drops into a recess formed in the chair for that purpose; a vertical pin from the outside, and extending downwards in such a form that, when the keys are placed one on each side of the rail, the pins meet underneath; and on being dropped vertically (in this position) into the chair, the pins exactly fit and completely fill the taper vertical slot in the chair. The heads of the keys are the same width as the chair, except at the joint chairs, where they are made wider, so as to act as fish plates. In order to keep the keys and rail in their position, and to prevent the rail from rising, the patentee drills or forms a hole longitudinally (in the direction of the rails) through the chair beneath the rail, and forms a corresponding hole through the ribs of the keys (half in each) at the point where they meet under the rail, and he drives a pin through the chair and the keys, and thus secures the whole firmly together. The chair is fastened to the sleeper in the ordinary manner. *Patent completed.*

848. D. S. SUTHERLAND. *Improvements in protecting vessels of war and fortifications from the effects of projectiles.* Dated April 2, 1863.

Sand, when securely confined within boundaries which prevent its escape from a pressure applied to it, is practically incompressible, and from the mobility of the particles composing it, is capable of transmitting and distributing a pressure or blow given to any part of a mass so confined over the whole or greater part of such mass. These properties of sand may with great advantage be employed in combination with armour plating as a means of protecting surfaces from the effects of projectiles. The arrangements employed for these purposes may be greatly varied. *Patent completed.*

849. J. CASSELL. *Improvements in stills for the distillation of petroleum and other heavy oils.* Dated April 2, 1863.

This invention is not described apart from the drawings. *Patent completed.*

850. J. J. PÜTEL. *Improvements in furnaces and fireplaces having for object the consumption or prevention of smoke.* Dated April 2, 1863.

This invention is applicable to fireplaces of all kinds, whether for furnaces, domestic stoves, or others. The invention consists in constructing fireplaces and furnaces with no outlet for the products of combustion except through apertures made at an angle of 45 degrees, more or less, in a bridge or wall at the back of the fireplace. The gases evolved from the coal or other fuel used, mixed with atmospheric air, pass through or over the incandescent fuel, then through the apertures in the bridge. The gases pass through these apertures in a state of flame, and are used for heating purposes at the back of the bridge. *Patent completed.*

851. W. JONES. *Improvements in the construction of ships or vessels, part of which improvements are also applicable for constructing buildings and for various other purposes in which rolled iron is employed.* Dated April 2, 1863.

This invention relates mainly to rolling bar or angle iron with shoulders or recesses against or in which corresponding parts of a contiguous bar will fit and add greatly to the strength, rigidity, and stiffness of the structure. For many parts of iron ships the iron is to be rolled with a recessed shoulder against which the edge of the contiguous plate will butt, and thereby offer a considerably greater resistance to end-pressure than when a joint simply depends on the rivets. *Patent abandoned.*

852. G. A. COX. *Improvements in the treatment or preparation and manufacture of jute, hemp, flax, and other fibrous or textile materials.* Dated April 2, 1863.

This invention relates to the arrangement and construction of various mechanical contrivances to be used for snipping, teasing, hackling, cutting, breaking, and otherwise treating as a part process of the manufacture thereof, jute, hemp, flax, and other fibrous or textile materials, such operations being anterior to those relating to the spinning and final manufacture into fabrics of the fibrous or textile materials hereinbefore referred to. According to one modification of the machinery or apparatus involved in carrying out the present invention, the contrivance for holding or gripping the jute, hemp, flax, or other fibrous material, consists of two endless grippers or holding sheets, made of hemp or other fibrous material, gutta percha, caoutchouc, leather, chain, wire, or other flexible substance. These grippers or holders work over grooved or plain pulleys or carrying rollers, one being situated at each end of the loop or bend of the grippers which operate in a horizontal direction. These traversing grippers are disposed in an open frame which carries the bearings for the pulleys, one gripper being directly above the other, the two being set to work parallel with each other and in contact. The lower endless gripper is made considerably longer than the upper one in order that a space may be left at each end of the longer one to act respectively as feeding in and delivering tables. Both the upper and lower grippers traverse continuously in the same direction; and if a firmer hold upon the fibre is required, that effect can be secured by adjusting the levels of the roller centres closer to each other, the projections of one coinciding with the grooves or recesses of the other. Immediately above and beneath the point where the hackle or gill of the cylinders, travelling gill sheet, or combs work upon the fibre for the opening or disintegrating process, there are disposed curved plates or other fixtures to afford the grippers or holders a superior strain or more powerful hold upon the fibre. There are also adjustable rests placed in front of the holders or grippers to give the necessary length of nip or holding pressure. Parallel to the travelling grippers or holders, so far as snipping, teasing, combing, or hackling are concerned, there is disposed a cylinder or cylinders, or revolving sheet, or combing arm, running either with or against the direction of traverse of the fibre, as may be necessary, these details being fitted with hackle pins, gill pins, or whatever pointed or blunt instruments may be necessary for the further treatment of the fibre. As the fibre is fed into the gripper or holder, the attendant allows the end of the fibrous mass to hang over the edge to the extent to which it is intended to be hackled, snipped, teased, or combed; it is carried along by the lower gripper until it is conveyed between it and the upper gripper. Here it is secured and carried along over the face of the cylinders where the operations of hackling, snipping, teasing, and combing are accomplished. *Patent completed.*

853. A. P. PRICE. *Improvements in apparatus employed in the fusion, manufacture, production, and refining of metals.* Dated April 2, 1863.

This invention consists in so constructing cupolas, blast furnaces, or other similar furnaces employed for the manufacture, fusion, or production of cast iron, steel, or other metals, and crucibles, or other similar vessels employed in the conversion or refining of cast iron, in the manufacture and production of iron or steel by the injection of air or gases, or by that process known as the atmospheric process, that they shall be surrounded either entirely or partially with a hollow casing of cast iron, or of malleable iron, or other suitable metal, and shall be so constructed that a current of water or jet of steam, or a blast of air may circulate freely through and around such hollow casing, by which means the sides of the cupola, blast furnace, crucible, or other similar converting vessel may be cooled, and the lining of the cupola, blast furnace, crucible, or other similar converting vessel may be preserved from the destructive action of the heat and the fluxes. When this casing is applied to crucibles or converting vessels used in the conversion of cast iron into steel or iron, and require to be moveable, the patentee prefers to construct the casing in such a manner that it shall be closed with the exception of suitable inlet and outlet pipes, so that no water, steam, or air shall escape except by such outlets when the vessel is moved for the purpose of discharging its contents. The inner surface of the casing may be lined with fire-brick or fire-clay, or any other suitable material. *Patent completed.*

854. A. B. SKITHEN. *Improvements in casings, covers, or wrappers for bottles, jars, and other articles.* Dated April 2, 1863.

Instead of making the wrapper so as to cover the top or neck of the bottle or other article, as hitherto practised, the patentee leaves the wrapper open at the top, so as to allow the whole or part of the neck of the bottle or other article to project beyond the wrapper, whereby considerable economy is effected in the quantity of the material of which the wrappers are made, and other advantages are obtained in the packing, storing, and handling of the bottles or other articles. He makes these wrappers or covers of rushes, or of straw, or of any other suitable vegetable substance or material; and if formed of machine straw, or of hay, or other broken or short-fibred substance, he converts the same into strands, lines, or ropes tied spirally or otherwise with twine or string. He arranges the rushes or other substance, or the strands, lines, or ropes made of the same, round a form corresponding with the shape and size of the bottle or other article for which the cover may be intended; or he winds the strand, rope, or line spirally round the former, and he then sews by hand or machinery, or ties or otherwise binds or secures the strands, layers, or ropes together; or he first forms the material into mats sewn by hand, or by machinery, or otherwise tied or secured, and subsequently converts the said mats into covers or wrappers. When the material of which the wrappers are to be made is so sewn or stitched by machinery, the said material is spread or ranged upon strips or pieces of paper, calico, or other woven fabric to facilitate the forming of the stitches. *Patent completed.*

855. A. STEWART. *Improvements in saddles.* Dated April 4, 1863.

Instead of fixing the saddle in the usual permanent way to the saddle tree, it is, according to this invention, contrived so as to be connected thereto or disconnected therefrom at pleasure, and it can in consequence be conveniently stuffed in a more uniform manner, and to a greater depth when required for horses with high backbones, whilst there is not the increased hardness at the after part, which is unavoidable with the mode of fixing hitherto adopted. For the purpose of attaching the pannel to the saddle tree, the former has fixed in it near its outer edge at suitable points certain metal sockets or nuts screwed to receive thumb screws, which are inserted from the upper side of the saddle through eye-plates fixed into the saddle tree. The screws are by preference formed with slotted thumb heads for turning them by, and two of these which are at the front part of the saddle serve to receive cloak straps, and dispense with separate staples for that purpose. At the crupper a metal staple is fixed into the pannel, and a screw is passed through an eye in this staple, and is screwed into a socket or nut firmly fixed into the back of the saddle tree. The back of the saddle tree is by preference shaped squarely down, instead of being acutely bevelled off, as in most British saddles; and this facilitates the application of the staple and screw, and permits of the bearing surface upon the horse's back being comparatively larger for a given size of seat. When a crupper strap is used, the crupper screw is formed with a slotted thumb head through which the strap is inserted; a separate staple may, however, be fixed to the back of the saddle for the crupper strap. *Patent abandoned.*

856. J. BLAIR. *Improvements in the finish of threads and yarns.* Dated April 4, 1863.

In carrying out this invention, the patentee makes a compound or mixture similar to soft soap from any of the fixed fatty oils, such as olive, palm, or similar substances, the same to be saponified by being boiled with a metallic oxide, such as caustic potash, and also salt. To this mixture or compound may be added spermaceti, lard, white wax, paraffin, or similar articles, to give additional softness to the yarn or thread. For fine yarns the proportions used are—oil and caustic potash and salt about 90 parts, lard and white wax 10 parts; for coarse yarns—80 parts of soft soap and salt, and of white wax, olive oil, lard, &c., 20 parts; in each case to be diluted with water, say about three-fourths to one gallon to each pound weight of the mixture, as experience may find best. The rove, when being spun, must be passed through the said mixture whilst in a warm or dissolved state (which can be accomplished by steam or other similar means, but a steam bath is preferred), and reeled at once (without being dried by a stove), and then placed on a stretching machine, and after about fifteen or twenty minutes' gentle pinning the yarn will be ready for use in the loom without boiling or dressing. Yarn for linen thread must be twisted through the mixture the same as yarns for weaving, and finished in the usual way; but threads for sewing machines should be passed through the mixture (after being twisted and dyed) in a cold state for at least twice, and then remain in the polishing machine for about ten minutes or so. *Patent completed.*

857. P. HANREZ. *Improved machinery or apparatus for drying coal, grain, and other substances.* Dated April 4, 1863.

This improved machinery or apparatus consists of a central shaft or axis mounted in a step or socket in such a manner as to allow of a sufficiently rapid motion being imparted thereto to throw off, by the effect of centrifugal force, the water contained in the coal or other matters under treatment. On this shaft is fixed a circular ring or crown, to which is attached a frame covered with wire cloth, or perforated sheet metal, the holes being of such diameter that the water will escape through the same while the coal or other matters are retained. The water which escapes through the casing is projected against an outer casing of sheet iron, which surrounds the apparatus, and which throws it down into a reservoir, from which it is let off by a cock. Concentrically with the aforesaid shaft is fixed a hollow shaft which turns rapidly in the same direction as the former (or inner shaft), but with a different velocity. This hollow shaft serves as the axis to a spiral screw or helix, of which the exterior diameter is equal to that of the interior of the perforated cylinder. This screw, turning as aforesaid with a different velocity, lesser or greater than that of the drum or cylinder, the coal or other matters being continually fed into the apparatus by means of a hopper, will fall first on to the top thread of the screw, which is slightly curved upwards or flanged in order to collect or throw over the matters more quickly. By the rapid rotation of the aforesaid screw, the coal or other matters are thrown against the sides of the drum, down which they fall vertically while being deprived of their moisture, and reach the bottom dry, falling into a reservoir adapted for the purpose of receiving them. The rapidity of the descent of the matters fed into the drum along its sides will be proportionate to the difference between the rate of rotation of the drum and that of the screw, and the pitch of the screw being determined, this difference may be determined so as to ensure the coal or other matters remaining in the apparatus until perfectly dry. *Patent completed.*

858. J. SILVESTER. *Improvements in attaching guards to pressure gauges.* Dated April 4, 1863.

This invention consists in making the guard in one piece with the rim, by which the glass plate is held in its place in front of the dial plate, the rim and guard being made

in one piece either by casting or stamping. Or the rim and guard may be made in separate pieces, and joined together by soldering, screwing, rivetting, or otherwise. Or the guard may be made separate from the rim, but of such a size that it will fall into or enter the said rim. In this case two pins or screws are inserted in a radial direction in the rim, and opposite each other, and a notch is made in the edge of the guard. By inserting the edge of the guard under one of the said pins or screws, and causing the notched part of the edge to pass the other pin or screw, the guard may be brought underneath the said pins or screws. By now turning the guard until the notch in its edge is not opposite either of the pins or screws, the guard is securely fixed in its place. By this last described improvement the guard may be readily removed for the cleaning of the glass. Or the guard may be placed on the front of the rim and secured thereto by screws. *Patent abandoned.*

859. W. H. Perkin. *Improvements in the manufacture of red and orange colouring matters.* Dated April 4, 1863.

It has before been proposed to act on a salt of napthalamine with nitrate or potash, or other nitrate, so as to obtain a red or orange colouring matter; but the process has been of no commercial value, as the reaction when these two substances only are employed is incomplete and variable, besides which the proper purification of the colour has not heretofore been effected. According to this invention, the inventor employs, in addition to the salt of napthalamine and the nitrate, an alkali or basic substance, capable of taking some of the acid from the salt of napthalamine. He employs in practice the hydrochlorate of napthalamine, nitrate of potash, and potash; and to two equivalents of the first he adds one equivalent of each of the latter; immediately chloride of potassium is formed, and one equivalent of nitrous acid is left to act on two equivalents of napthalamine, the required colouring matter is precipitated, and it may at once be used as a pigment for printing, or it may be dissolved in alcohol and used as a dye. The colour, however, is much improved by purification, which is effected by washing it with water, then dissolving it in alcohol or other solvent, and crystallizing it out therefrom. To produce the purified pigment, the inventor precipitates a solution of the purified colour by means of water. *Patent abandoned.*

860. W. E. Gedge. *Improved apparatus for bolting flour.* Dated April 4, 1863.

This apparatus is composed of the ordinary bolter, covered with its cloth, with the addition of a wire gauze cylinder within it. On leaving the mill the undressed flour is received in the cylinder or inner bolter, which permits the flour to pass through its web, but retains both the fine and the coarse bran when they arrive stripped of flour at the opposite extremity of the cylinder. The flour which arrives alone in the second bolter is then bolted more regularly, and deposits a large quantity in the compartment reserved for the first. *Patent abandoned.*

861. G. Gimson. *Improvements in the means of actuating shuttles in looms for weaving narrow fabrics.* Dated April 4, 1863.

This invention relates to the means of traversing the shuttles through the sheds in the act of weaving narrow fabrics, in which process it is well understood several widths of fabrics are arranged side by side, and woven simultaneously, the several shuttles being mounted on a batten, and motion communicated by means of pegs entering and leaving the shuttles on each side of the warp, or by other means. These improved means consist in the application of a screw, or a series of screws, on the same shaft, one for each shuttle. The thread of such screw is of rapid pitch, and takes directly into the shuttles, sections of screws being cut therein for the reception of the thread. The screw shaft is rotated, first in one direction and then in the other, whereby the shuttles are propelled to and fro through the sheds formed in the warps, a shuttle being transferred from a screw on one side of the warp to the other screw on the other side. All the shuttles move in one direction at the same time, whereby, on one shuttle leaving a screw, it makes room for another shuttle coming or belonging to the adjoining warp. *Patent abandoned.*

862. A. V. Newton. *An improved construction of pressure gauge.* (A communication.) Dated April 4, 1863.

This invention applies, mainly, to the construction of gauges for gauging steam or water under high pressures. In carrying out the invention, a disc or plate of iron, or other suitable metal, is provided, having a recess or chamber for mercury on its under side, and pierced with a central opening for the passage of the mercury in its upward or downward movement. Fitted into a central recess of the disc is a cylinder of india rubber, which forms a bearing for a glass tube. Secured to the metal disc, and covering the same, is a cap having a shoulder for supporting a metal tube which surrounds the glass tube. A slot is made through the whole length of the metal tube, in order to show the height of the mercury in the glass tube, the same being indicated by a graduated scale. A metal cap, having a central opening is screwed to the metal tube, and serves to hold the glass tube in its place. A lateral hole is made in the metal disc for the insertion of mercury into the chamber below it. This hole, when the chamber is filled, is closed by a screw. A cylindrical cup is clamped to the under side of the central disc, and a diaphragm of india rubber is placed between it and the disc. A metallic plunger plays loosely in the upper and lower sections of the cup. The area of the upper portion of the plunger being much greater than that of the lower portion, allows of the mercury column being shortened. The downward movement of the plunger is limited by a shoulder in the cup. Attached to the under side of the cup is a coupling for admitting steam or water to act on the plunger. Between the cup and coupling is a diaphragm of india rubber, forming a tight joint, and on the upper surface of which rests the bottom of the plunger. The steam or water admitted to the gauge presses forcibly upon the lower part of the plunger, thereby forcing the mercury upwards in the glass tube in proportion to the pressure applied. As many times as the area of the lower end of the plunger is less than the area of the upper end of the plunger, so many times less will be the pressure per square inch upon the area of the upper portion of the plunger than upon the lower portion of the same plunger, thereby rendering practicable the employment of short columns of mercury for the measurement of high pressures without any other opposing medium. *Patent abandoned.*

863. P. Spence. *Improvements in the manufacture of sulphuric acid and sulphate of iron.* Dated April 4, 1863.

This invention has for its object the saving of the waste vapours arising from the manufacture of sulphuric acid, and the production by such saving of sulphate of iron. To effect these improvements the inventor causes the waste vapours to pass through masses of metallic iron in the condition of porous cakes, whereby the said gases are absorbed, and sulphate of iron is consequently produced. The condition of metallic iron above referred to is attained by submitting its oxides or ores to heat, so as to reduce it without fusion. The finely divided metal which arises from this treatment, he also proposes to use for the manufacture of sulphate of iron, apart from the manufacture of sulphuric acid. *Patent abandoned.*

864. F. O. Bakewell. *Improvements in wicks for lamps.* (A communication.) Dated April 6, 1863.

The patentee claims—1, the construction of a hollow tubular lamp wick, having an internally napped surface to increase the capillary action, substantially as described; 2, making a hollow wick for lamps of a folded strip of muslin, or other textile fabric, by uniting the edges together with a paste or cement insoluble in the oil or other fluid to be consumed; 3, making hollow or tubular lamp wicks of muslin, linen, or other suitable material, with or without a nap on the inner surface, with a filling of cotton, wool, bibulous paper, paper pulp, or other substance possessing the requisite degree of capillarity, as described. *Patent completed.*

865. B. Cooper. *Improved apparatus for feeding scribbling or carding engines.* Dated April 6, 1863.

This invention is not described apart from the drawings. *Patent completed.*

866. T. Burrow. *Improvements in, and machinery for, combing or dressing silk, flax, wool, hemp, China grass, or other fibrous materials.* Dated April 6, 1863.

This invention relates to improvements in machinery for combing, or dressing silk, flax, wool, hemp, China grass, or other fibrous materials, and consists in the employment of two revolving combs, which comb both ends of the fibre before it leaves the machine. *Patent abandoned.*

867. W. E. Gedge. *Improvements in aerial machines.* (A communication.) Dated April 6, 1863.

According to this invention the car acts as ballast, and holds the balloon in an almost horizontal position. It contains a steam boiler, water, coal, and the apparatus required for the aerial voyage. A rope ladder furnishes the means of ascending to the fore part of the balloon, and at the same time holds the fore part of the car suspended to the fore part of the balloon. From the fore part of the car a capstan or windlass may be turned on, which enrols the lower part of this ladder, shortening or lengthening it so as to make the car weigh down the balloon more or less to the front or rear, accordingly as it is desired to ascend or descend. In front of the balloon is a small case serving to maintain the bearing. The rear or stern part of the car is suspended to the stern of the balloon by a pipe of aluminium, which conducts the steam to a machine fixed to the same piece as the bearing at the stern of the balloon. The piston of this machine communicates directly with a connecting rod fixed to a shaft which traverses the balloon in its entire length. This machine acts on the connecting rod, and causes the shaft and the entire balloon to turn. Another rope ladder leads from the car to a case near the machine, and another capstan or lever holding the two ends of the rudder cords at the stern of the car permits oblique divergence to the right or left. The body of the balloon is of ovoid form; the smaller end passes first, and the larger end, having greater ascensional power, supports the bearing fixed to the machine, the rudder, and the oblique sails. These sails should present a surface of at least twice the thickness of the balloon, so that in turning they will press upon twice as much air as will oppose the end of the balloon. These sails, however numerous, may be all closed simultaneously by pulling a rope from the car during the progress of the balloon, and, on pulling another rope, the catch which holds the sails closed falls, and they open of themselves under the pressure of the wind. The object of this arrangement is to change the speed without interfering with the steam, as the balloon itself acts as a flyer, and it is desirable not to interfere with its regular march. Presuming that these sails when fully opened describe a course of twenty yards, it will follow that every stroke of the balance beam will drive the entire aerial apparatus twenty yards forward. The balloon may also be constructed entirely in the shape of a screw with the above arrangement. *Patent abandoned.*

868. M. Henry. *Improvements in probes, catheters, and similar surgical instruments.* (A communication.) Dated April 6, 1863.

According to this invention, it is proposed to manufacture probes, catheters, and similar instruments of vulcanized caoutchouc, instead of the materials usually employed. Also, according to this invention, probes, catheters, and like instruments may be constructed in such manner that they may penetrate to the part required without the aid of a mandril, or other rigid instrument, and yet be sufficiently flexible to pass suitably through the person. For this purpose the instrument may be made sufficiently flexible in the body, but terminate in a stiffer and tapering or more slender end at the entering extremity. An improved catheter or instrument may be constructed of a piece of vulcanized caoutchouc, or like substance, made tubular, or with a passage in it, such piece being of considerable thickness of material, or with thick sides comparatively to the bore of the passage, and terminating at the end to be introduced into the person in a solid portion, which may be tapering, conical, or thinner towards the extremity. According to this invention, the outer end or mouth of catheters or similar instruments may be of a conical or bell-mouth form, and fitted with a vulcanized caoutchouc or other elastic stopper, attached to the instrument by a cord or like connection to keep it from being lost. The instrument may be prevented from entering too far into the person by attaching to it a sheath or stall, which is fitted on the penis or other part, and kept there by lacing or otherwise. *Patent abandoned.*

869. J. Railton and H. Booth. *Improvements in machinery for carding cotton and other fibrous substances.* Dated April 6, 1863.

The object of this invention is to keep the surface of the main cylinder of carding engines clean while at work, and to obviate the necessity of stopping the engine occasionally for the purpose of stripping the main cylinder. In performing this invention, the inventors apply a fancy roller to the main cylinder, which fancy roller is covered with straight card teeth or needle points radiating from the centre. The surface of the fancy roller runs at a greater speed than the surface of the main cylinder; consequently, the action of the fancy roller looms the fibres on the main cylinder, so that when the fibres are carried forward to the top flats or worker and clearing rollers, they are in a fit state for being carded, and then deposited on the doffer. *Patent abandoned.*

870. J. Burwin. *Improvements in pickers, and in the means or apparatus employed in the manufacture thereof.* Dated April 6, 1863.

This invention relates to pickers made of sizing or prepared animal hides, which heretofore have been made with sharp angles, on account of the method adopted in their manufacture, and which sharp angles are very objectionable in use, as they cut the straps and catch the weft, which is thereby damaged. These improvements consist in rounding or removing these sharp angles, which is effected by means of dies or moulds properly formed, into which the pickers are placed, and pressure applied thereto by lever, screw, or other suitable means of applying pressure. The apparatus employed cannot be described without reference to the drawings. *Patent completed.*

871. E. T. Hughes. *Improvements in machinery or apparatus for manufacturing the ornamental tips of parasols, umbrellas, and other similar articles.* (A communication.) Dated April 6, 1863.

We cannot here give space to the details of this invention. *Patent abandoned.*

872. J. Swinburne and J. Stanley. *Improvements in steam engines and generators.* Dated April 7, 1863.

The first of these improvements provides a new mode o actuating the slide valve of steam engines, giving thereto a differential movement, and the power of reversing very similar in effect to that of the link motion hitherto in extensive use. The arrangement for carrying out this, is to fit an annular shaft or tube upon the crank shaft or axle of any steam engine (or upon another shaft that takes motion therefrom), loose to move without the shaft a limited distance in a rotating direction only, such annular shaft having two trunnions or pivots opposite to each other, so arranged as to form an axis for and to carry a sort of gimbal or annular disc. The gimbal or disc so carried is rendered capable of being set in any required position, and there held by means of a connecting link, one end of which is attached to the gimbal near the periphery about midway between the pivots, and the other end attached to a gland or sheave free to move (longitudinally only) upon the annular shaft by means of a forked lever or guide taking into a groove or clasping the gland or sheave. By this arrangement the gimbal can be set either to run true with the shaft, or take a wabbling to-and-fro motion in the direction of the axle line. This wabbling to-and-fro motion is made to give motion to the slide valve through the medium of a sort of bell crank and connecting rod, or by any other convenient means. When the gimbal is set at right-angles with the main axle line, the slide valve will be at rest; and when it is set at an oblique angle one way, the valve will move right for forward action, and when set the contrary way for backward. The limited rotary motion allowed to the annular shaft gives the required lead to the valve by means of a segment of a spur wheel taking into and passing out of a spur wheel fitted tight upon the annular shaft, or to the gland or sheave. In the latter case, the spur segment is of greater width to allow the movement of the sheave without missing the gear. Another method is to place the pivots that carry the gimbal at an oblique angle with the axle line, so as to give the short travel to the slide valve when the face of the gimbal transverse to its axis is set at right angles with the main axle line, as is obtained by setting the die in the centre of the link in ordinary use. In this case, the exact movement produced by the link motion is obtained without giving the lead by moving the annular shaft as described. *Patent completed.*

873. H. Gilbee. *A new composition for dressing and preparing silk, cotton, and woollen tissues and fibres, and also mixtures of the same.* (A communication.) Dated April 7, 1863.

This invention consists of a new industrial product composed of the following materials—1, Brazilian tapioca; 2, fig juice; 3, pearl moss; 4, vulcanized caoutchouc; 5, the juice of mulberry leaves. This composition can be applied to dressing and preparing all kinds of tissues made of silk, wool, or cotton, and of mixtures of these substances. It can also be applied to facilitating the winding of all fibres which have to be spun, wound, or twisted. *Patent abandoned.*

874. A. C. Bamlett. *Improvements in reaping and mowing machines.* Dated April 7, 1863.

The first part of these improvements relates to such reaping and mowing machines as have the pole to which

the horses are attached fixed to the machine by a universal joint, being designed to facilitate turning at the corners of the field, and to prevent accidents, and consists in controlling the movement of the pole by means of chains or projections fixed on the pole and fore part of the frame, so as only to allow the pole to turn to about right angles with the frame of the machine, or about parallel to the cutter bar. 2, In order to alter the "pitch" of the ordinary platform commonly known as Hussey's, the patentee mounts it in a frame which is jointed near the front edge of the platform. The frame is acted on by cranks, levers, or their equivalents, and by these means the pitch of the platform can be varied as required. *Patent completed.*

875. J. Macintyre. *Improvements in the manufacture of knobs, and other articles in china and earthenware.* Dated April 7, 1863.

This invention consists in giving an oval form to such knobs or other articles by turning after they have been formed by throwing, or otherwise; and for the purpose of turning such articles, the patentee employs a lathe provided with a chuck capable of producing ovals of various proportions, and of readily changing from such chuck to the circular chuck when producing circular stems or other parts to such description of knobs or other articles. And in order that the articles produced may be of uniform size and shape he prefers to employ tools, the cutting edges of which are suitably formed to produce the shapes desired, such tools being supported by guides and working up to a stop as heretofore practised when turning certain descriptions of circular articles. The invention also consists in producing balls, handles, grips, hat pins, and other similar articles suitable for door furniture, and other like uses, of a reeded, fluted, or other ornamental form, by turning. For this purpose he employs a template of the form desired, mounted upon one end of the spindle of the lathe head. This spindle at the end upon which the template is mounted is supported by an arm capable of movement upon an axis of motion, and the template is borne up to a pulley or follower fixed to the framing of the lathe by a string or other suitable means; the template can be thrown out of action when it is desired to employ the lathe for producing ordinary circular work. *Patent completed.*

876. J. H. Johnson. *Improvements in machinery or apparatus for drying grain, applicable also to the manufacture of malt.* (A communication.) Dated April 7, 1863.

According to this invention, it is proposed to employ a revolving screen of fine wire work, perforated metal plates, or other suitable material, and of any length and section, but strengthened by means of longitudinal external rods and transverse rings or annular frames at the ends and middle of the screen. This screen is provided with internal spiral blades, and with a hollow trunnion, through which latter the grain to be dried or desiccated is allowed to enter the revolving screen from a stationary hopper provided with a regulating slide. Beneath this screen—which is enclosed on all sides by a metal casing—there is a small stove from which pipes or flues conduct the heat to a chimney, after first traversing to and fro beneath the screen, so as to disperse the heat uniformly under the grain. This stove and pipes are protected by a shield or covering which prevents any particles of dust or refuse grain from depositing upon the stove and pipes. The refuse grain and dust are caught by an endless travelling band beneath the screen, and carried away to a spout, a revolving brush being employed for removing thoroughly the dust from the band or belt. Metal conductors are placed above the band to conduct the dust and refuse on to it as they fall from the screen. The grain is agitated by the revolution of the screen, and the heated air passing through it carries off the moisture and escapes with it by a hood or cowl at the top of the outer casing. The dried grain escapes from one end of the screen, which may be provided with regulating doors for that purpose, or left quite open, and falls into a lateral conducting spout. *Patent abandoned.*

877. J. H. Johnson. *Improvements in polishing precious and other hard stones, and in the machinery or apparatus employed therein.* (A communication.) Dated April 7, 1863.

This invention consists, essentially, in polishing the above-named substances without the intervention of polishing powders or substances of any kind between the wheel and the stone under treatment. The polishing wheel is composed of fine grit stone, and the dust produced is removed from the stone by a ventilator or brush, slightly wetted, being occasionally applied to the wheel for the purpose of preventing it from overheating. *Patent abandoned.*

878. R. A. Brooman. *Improvements in the manufacture of baryta and its derivatives, in obtaining by-products, and in revivifying or recovering certain agents employed in such manufacture.* (A communication.) Dated April 7, 1863.

The details of this invention are too voluminous to be quoted here at sufficient length for an intelligible abstract. *Patent completed.*

879. R. A. Brooman. *Improvements in reproducing or obtaining fac-similes of the veins, pores, knots, and figures of wood upon paper and other surfaces.* (A communication.) Dated April 7, 1863.

This invention consists in covering a smooth plank or piece of wood with a coating of paint, which is made to penetrate the pores and veins thereof; in the removing with a scraper or otherwise all the paint remaining upon the smooth surface of the wood, leaving only such of the paint as has penetrated the pores and veins; in coating a very thin plate of copper or other metal on both sides with a thin layer of wax; and in applying this metal plate upon the wood prepared as before described. The metal plate is pressed strongly upon the wood by a roller or otherwise, and the paint is thus forced from the pores or veins of the wood and adheres to the wax upon the metal plate. The plate is then removed from the wood, and all the parts of the wax to which the paint has adhered are carefully scratched off with a sharp-pointed instrument, so as to expose the metal beneath those parts. The plate is next plunged into a bath containing nitric acid or aquafortis; the acid enters all the parts from which the wax has been removed, and bites through them. All the pores and veins of the wood are thus reproduced by the spaces bitten out of the metallic plate. The plate is washed with water to cleanse it, and the wax is removed by a bath of essence of turpentine or other spirit. The metal plate thus prepared serves for the reproduction of the veins, pores, knots, and figures of wood upon any surface, whether previously prepared by oil, paint, or otherwise. For instance, the plate is applied upon a surface painted with a ground colour, and a brush charged with paint of the colour of natural veins and knots is passed over the plate; the paint passes through the spaces or openings in the plate and adheres to the surface beneath such spaces or openings only, and thus an exact copy of the veins, pores, knots, and figures of the wood is obtained. *Patent completed.*

880. J. Howard, E. T. Bousfield, and J. Pinney. *Improvements in steam engines and in the means of applying the same to the tilling of land, also in apparatus to be used with such engines in the tilling of land.* Dated April 7, 1863.

This invention is not described apart from the drawings. *Patent completed.*

881. A. V. Newton. *Improvements in projectiles for ordnance and in fusees therefor.* (A communication.) Dated April 7, 1863.

The first part of this invention relates to the employment of fulminates of silver and mercury, and other fulminating compounds, for the bursting charges of explosive projectiles, its object being to obviate the accidental explosion of such charges in the handling or transportation of, or by the dropping of, the projectiles. To this end it consists in the use—either mixed with the fulminate, or interposed between small quantities of the fulminate so employed—of cotton, gun cotton, curled hair, wool, flocks, saw dust, or other soft fibrous or granular substance, to reduce the force of the concussion between the grains of the fulminate; also in lining the charge chamber of the projectile with woollen, cotton, or other cloth or flannel, or other soft material for the same purpose; also in the division of the charge into a number of parts by means of rigid partitions in the chamber, whereby the force of the concussion produced between the particles of fulminate, in case of dropping the projectile or subjecting it to severe concussion, is reduced. The second part of the invention relates to the use of metallic packing for the prevention or reduction of the windage between the projectile and the bore of rifled ordnance, and for obtaining a rotary motion of the projectile in its passage through the bore; and it consists in an improved arrangement of a flanged follower, in combination with an expanding, concave, convex, or conical packing ring. The third part of the invention relates to percussion fusees for the ignition of the bursting charges of explosive projectiles, and consists, principally, in the construction of a percussion fuse tube or plug with two separate chambers, one to contain fulminate of silver or mercury, or other fulminating powder, and another to contain sand, emery, broken glass, or any other hard granular substances, the chambers being so arranged and combined (by means of a lock of simple construction) as to be perfectly closed and locked to prevent communication between them until the firing of the charge of the piece of ordnance from which the projectile is to be thrown. The unlocking is effected by the impact produced upon the projectile by the explosion of the charge, and thus communication between the two chambers is opened for the admixture of their contents. *Patent completed.*

882. G. and W. R. Hill. *Improvements in steam boilers.* Dated April 8, 1863.

This invention consists in forming in the internal flues of steam boilers one or more water-tight compartments, which act as stays, and also provide additional heating surface. *Patent abandoned.*

883. W. Simpson. *Improvements in insulating the magnetic needle or needles in compasses.* Dated April 8, 1863.

This invention relates to all magnetic needles used in mariners', azimuth, and other compasses, and has for its object the insulation of such magnetic needles that they will practically be insensible to or uninfluenced by local attraction. *Patent abandoned.*

884. J. Moshkimer. *Certain improvements in machinery or apparatus for crushing, grinding, and dressing metallic ores, quartz, and other similar substances.* Dated April 8, 1863.

This invention relates—1, to the crushing of auriferous, argentiferous, or other metallic ores; and 2, to the separation of the valuable portion from the inferior portions thereof. The improvements consist—1, in the employment and use of a heavy metallic crushing weight, hammer, or stamp, which is attached to a vertical shaft, upon which adjustable tappets are secured, and which are acted upon by lifting cams in such a manner as to lift the hammer and allow it to fall by its own weight, the angle of the cam effecting the partial revolution of the hammer or stamp at each stroke, so as constantly to present a different surface to the ore, which is supplied beneath the hammer upon a die or foundation, the whole being enclosed in a casing or mortar; the crushed ore issues therefrom by means of a screwed aperture with a wood partition on the opposite side, so as to keep away the pressure of water against the screen, which is provided with an outlet at the bottom to regulate the height of the water in the mortars. When crushing wet ore, a space is left in this mortar lined with copper, and amalgamated with mercury, so as to retain any gold or precious metal that may come in contact therewith. A second part of the invention relates to an arrangement of apparatus for separating the finely crushed particles from the rougher or coarser portions, and consists in the use of a chamber divided into compartments, each having a stream of water passing through it. The pulverized ore is admitted to the part of the chamber above the partitions, and at right angles to the course of the water stream, so that the heavy portion of the ore falls into the first compartment, the lighter and finer into the second, and so on, where they subside to the bottom, whence they may be removed by means of a pipe and tap. A third part of the invention relates to the further separation or dressing of the ore, and consists in a number of "hopper" or delivery boards, one supplying the table with the pulverised ore, and others supplying water thereto. The table is suspended at an angle, and caused to reciprocate laterally by means of an eccentric, or cams and rod, so that the ore is evenly spread over the surface at the upper edge of the table, but by the reciprocating motion the valuable portion accumulates at one side of the table, the middle quality nearer the centre, and the inferior portion at the other side, the discharge thereof being continuous. *Patent completed.*

885. J. N. Brown. *Improvements in securing or connecting the bearing springs of railway carriages and waggons to the axles boxes of the said carriages and waggons.* Dated April 8, 1863.

According to one of these improvements, the patentee substitutes for the spring rivet an eye-bolt, the head of which eye-bolt passes through the top of the grease chamber in the axle box. A bolt or pin is passed through the side of the axle box, underneath the top of the grease chamber, and through the eye of the eye-bolt. This being done, the nut of the eye-bolt at the top of the spring is screwed up, and the spring is then firmly secured to the axle box. Another of these improvements consists in extending the lugs which form part of the spring box a sufficient distance down the sides of the axle box to enable a bolt to be passed through the said lugs and underneath the top of the grease chamber, as before. Or, instead of using a bolt, the same object may be accomplished by using a screw pin on each side of the axle box, the said screw pins being tapped into the axle box. *Patent completed.*

886. T. Gray. *Improvements in preparing and bleaching jute and other vegetable fibres for spinning and other purposes.* Dated April 8, 1863.

The patentee claims—1, the omission of boiling material in alkali before bleaching it; 2, the mixing of soda ash or other alkali with the bleaching liquor before the material is immersed in it, the material being thus rendered considerably stronger than that bleached by the ordinary process, and whereby it acquires a permanent snow-white colour. *Patent completed.*

887. J. R. Harris. *Improvements in propelling vessels.* Dated April 8, 1863.

This invention relates to giving motion to vessels by means of propellers enclosed within the body of the vessel, except at those parts of them which are for the time acting on the water for the purpose of propulsion. The inventor forms the propellers with radial or other suitably formed floats or boards, and with enclosed sides, so that the space between adjoining floats or boards may form chambers open at the periphery for action upon the water; and he encloses these propellers—except where they act directly upon the water—within boxes or compartments formed for them in the hull of the vessel. By these means, only the part of the propellers for the time acting projects from the vessel, and at the same time the back action of the water is avoided. Each of the propellers may be worked by a separate engine, or may be otherwise operated, in order to their being caused to revolve as required in the same or opposite directions. *Patent abandoned.*

888. W. E. Gedge. *Improvements in apparatus for propelling and navigating small craft.* (A communication.) Dated April 8, 1863.

The object of this invention is to employ scientifically in the navigation of boats, barges, and other small craft, the corporal power which boatmen and others in a great measure waste; also to render such navigation easy to those who have found difficulty in navigating with the ordinary means; and to obtain greater speed with no greater expenditure of power. One part of this invention consists of an arrangement of oars with jointed points. These oars are made in two principal parts—namely, a wooden shaft and a blade of metal, wood, or other suitable material. A half-circular socket fixed on the blade, and running nearly its entire length, receives one end of the shaft lengthwise; it is of conical shape, and the shaft passes into its entire length, lying flat on the side of the blade, and is held by the conical shape of the socket. It cannot vacillate in this sheath, no matter what strain is brought upon it by the tension of the handle. A ferule is fixed on the shaft towards the handle, its lower part hinging on a jointed pivot fixed on the side of the boat. By this arrangement the oar may be inclined at pleasure, and placed deeper into the water while moving, if desired. *Patent abandoned.*

889. W. H. Mitchel. *An improved construction of barometer.* Dated April 8, 1863.

This invention is not described apart from the drawings. *Patent completed.*

890. J. L. Norton. *Improvements in machinery for washing and drying wool and other fibres and rags, also tentering, stretching, and drying fabrics.* Dated April [illegible] 1863.

For the purposes of this invention, in washing wool [illegible] other fibres or rags, a trough or vessel having a perforated or false bottom is employed containing washing liquor [illegible] water. An endless sheet or band with projecting teeth [illegible] pegs is caused to move from end to end of the trough. The fibrous materials or rags are fed on to an endless apron which conducts them into one end of the trough; they are then, by the teeth or pegs on the travelling sheet [illegible] band, taken through the water or washing liquor, and discharged on to another endless apron at the other end [illegible] the trough, and by it they are conducted to a pair [illegible] pinching or squeezing rollers. After the wool or [illegible] fibres or rags have been washed and squeezed, they are [illegible] be dried by being spread on an endless sheet of wire [illegible] composed of parallel spirals or helices of wire run into [illegible] other, by which a very flexible endless sheet is produced

peculiarly fitted for this purpose. This endless sheet is placed within an enclosed chamber with doors at each end. When the wool or rags are first fed on to the endless sheet, the door at the feeding end is opened, and as soon as the entire sheet is filled with wool or rags, the door is closed until the wool or rags are sufficiently dried. Both doors are then opened—that is to say, the doors at the feeding and delivery ends of the machine, and while the dry wool or rags are being discharged from the sheet at the delivery end of the machine, wet wool or rags are fed into the feeding ends of the machine until the whole is again charged with wet material, and then the doors at each end are again closed until the material is dried, and so the process is repeated. In tentering, stretching, and drying machines, where the endless chains move in upright or horizontal guides, the patentee encloses the chambers containing them, and applies coils of pipes fixed between the cloth to be dried and steam jets, in a similar manner to that above described, by which such machines are made more advantageously than heretofore. In place of gearing the rollers over which the endless chains of tenters pass by means of spur wheels on the axes of the rollers with intermediate spur wheels between the succeeding rollers, he applies a single shaft, and gives motion therefrom to the rollers by bevel toothed wheels on such shaft, and on the axes of the rollers. In order to suit the rollers of tentering and stretching machines more effectually than has heretofore been done to receive varying widths of fabrics at different times, he constructs each roller of three parts, and each part is formed with parallel bars, leaving spaces between the parallel bars, in order that the bars of the two outer parts of a roller may slide between the bars of the central or third part of the roller, whereby a roller—whether at its smallest length, or expanded to its greatest length, or to an intermediate length—will be of the same diameter. *Patent completed.*

891. A. KINDER. *Improvements in coating or covering lead, or alloys of lead, with tin or alloys of tin, and in the apparatus employed therein.* Dated April 8, 1863.

This invention relates to certain modes of coating or covering, lead, or alloys of lead, with tin or alloys of tin, on one or both sides, whereby the two metals or alloys may be perfectly united, forming one solid ingot, which is to be subsequently reduced to the desired thickness by the ordinary processes of rolling or beating. According to one method, the patentee first casts a plate of lead or alloy of lead in any convenient mould, and as soon as the metal or alloy is set, he removes it from the mould, and places it in a second mould upon a flat table. This second mould is made with moveable or adjustable sides, so as to be capable of contracting to any desired size. The sides are also adjustable in height above the surface of the table, in order that they may project more or less above the surface of the lead plate contained between them. He then casts upon the lead, whilst it is still in a heated state, a sufficient amount of molten tin or alloy of tin to completely cover the lead, the thickness of this covering being regulated by the height of the sides of the contractable mould above the lead. The surface of the tin is levelled and smoothed off whilst in a heated state by passing a metal or felt roller or sleeker over its surface; the roller running along the top of the two slides of the mould, any superfluous metal is thereby removed, and is ready for the process of lamination. *Patent completed.*

892. H. B. FOX. *Improvements in dish covers.* Dated April 9, 1863.

These improved covers are constructed of any number of scales or pieces formed by preference (when for round dishes) from sections of a hollow semisphere, connected together at the points by a joint in such a way that the scales or plates of the cover will fold into or over each other. An oval dish cover can be formed from scales or pieces which are portions of a semi-oval or compressed semisphere. The shape of the scales or pieces from which the covers for both round and oval dishes are formed may be of other shapes than those partaking of the arch, and the covers may be constructed of other forms than round or oval, and they may be made to open from the centre, folding down on each side of the dish; and oblong covers may be formed to open either longitudinally or transversely as desired. *Patent abandoned.*

893. D. J. COOKE. *Improved compounds or compositions for sizing, stiffening, and colouring yarns and textile fabrics.* Dated April 9, 1863.

For sizing and colouring worsted braid and fine cotton yarns the inventor mixes about 20 lbs. weight of farina or potato flour, 20 lbs. of sago flour, 15 lbs. of rice flour, and 6 lbs. of glue with sufficient water to make it of a suitable consistency, and adds to the said mixture or compound any suitable colouring matter to give the materials the desired tint or colour. The said mixture will be sufficient for about 112 lbs. weight of worsted braid. He makes gelatine size for stiffening grey, white, or coloured goods made of cotton, linen, or other fibrous materials, whether in the state of yarn or woven fabrics, by mixing about 280 lbs. weight of rice flour, 280 lbs. of wheat flour, 112 lbs. of farina or potato flour, 56 lbs. of sago flour, and 16 lbs. of glue with a sufficient quantity of water to make it workable, and adds the necessary colouring matter. *Patent abandoned.*

894. S. T. HEATH. *The application of glass for ceilings and the like overhead parts of houses and other structures.* Dated April 9, 1863.

Those parts of dwelling-houses, theatres, public and other buildings, such as the ceilings, the inside surfaces of roofs, the under surfaces of galleries, and other overhead parts, all which are usually constructed of lath and plaster, and those parts of ships, such as the cabin and state room ceilings, or, in other words, the under surfaces of decks, the lower part of screens, theatre scenes, and other like overhead parts, are, according to this invention, formed partially or wholly of glass, silvered, transparent, opaque, figured, coloured, or otherwise, but preferably silvered. *Patent abandoned.*

895. F. J. RISSE. *An improved haft or handle for holding tools or instruments of various sizes.* Dated April 9, 1863.

This invention consists in a combination of parts hereinafter described, by means of which one haft or handle is made capable of holding various sizes of files, joiners' chisels, and such tools or instruments as require hafts or handles. For this purpose the patentee screws the ferule, which is usually placed on the haft or handle, partially internally, and he chases a corresponding screw on that part of the haft or handle which is usually made of wood, to receive a portion of the ferule; the remaining part of the screwed surface of the ferule contains a cylindrical piece of metal, hollow or partially so, and secured on its outer surface to a pitch corresponding with that of the ferule. The cylindrical piece of metal contains jaws or nippers working on centres which turn on grooves cut in the cylindrical piece of metal above named. By this apparatus, when the "tang" of a file or other instrument required to be held is placed within the jaws or nippers above named, the jaws or nippers are made to hold the instrument fast by causing the ring of metal carrying them to come to such part of the ferule that the outer surfaces of the jaws or nippers press against the internal surface of the ferule, the various lengths of the "tangs" of different files and instruments being accommodated by a spring placed underneath a cover in the centre of the haft or handle. *Patent completed.*

896. G. SPENCER. *Improvements in preventing incrustation in steam engine boilers.* Dated April 9, 1863.

This invention consists in preventing incrustation in steam engine boilers in the following manner:—The patentee places on some convenient part of the boiler in connection with the steam space a close vessel of iron, or other suitable metal, of a cylindrical or other suitable form, furnished with a number of diaphragms or dishes placed in each vessel, one over the other. Through the centre or sides of such vessel he brings the feed water pipe, so that the feed water is discharged into the top dish or diaphragm, from which it flows into the next under through holes or spaces furnished with raised edges not quite so deep as the raised edges of the outside of the dish, so that the water may all pass into the next lower dish by such holes or spaces. There being a series of such dishes, the water passes from the feed pipe into the top dish, then from that through the spaces into the next lower dish, and so on through the whole series of dishes. The object of this contrivance is to catch and retain the salts held in solution by the cold water, and which are thrown down as a deposit on the boiling of the water in the dishes or diaphragms by the heat of the steam of the boiler, with which the whole inside surface of the vessel is always in contact. Or a series of dishes may be arranged having one with the longest diameter at bottom, and each one placed over this of a little less diameter than the one under it. These dishes have no holes or spaces in them; but the water passed by the feed pipe into the top dish flows over the raised edge of that dish into the one under, that when full into the next, and so on to the bottom one, and, lastly, in either case, through a hole in the boiler top and into the steam space of the boiler. As an additional security, he coats the surface of the inside of this vessel, and the dishes and the inside of the boiler and outside diameter of tubes or flues (if any), with a suitable substance, such as Green's oxide paint, to prevent the adhesion of the deposited metal. *Patent completed.*

897. A. HETT and F. W. BASSET. *Improvements in preventing the fouling of ships' bottoms and in cleansing the same when fouled.* Dated April 9, 1863.

The patentee claims the use of heated water, heated air, steam, or poisonous substances, vapours, or gases, whether heated or not heated, or smoke distributed over or upon or applied to ships' bottoms, for preventing the fouling thereof, and in cleansing the same when fouled. *Patent completed.*

898. J. RUDLEY, jun. and D. MCCOLL. *Improvements in preventing the escape of fumes and matters from furnaces.* Dated April 9, 1863.

For the purposes of this invention, the inventors propose to cause the current of gases from the furnace on their way to the chimney to pass through the interstices of some incombustible substance, broken into pieces of suitable size, so that the gases will, to a great extent, be deprived of the matter carried along with them by what may be termed filtration; and as the spaces between the brick, slag, or whatever incombustible substance is used, must necessarily be soon filled up, they propose to arrange the material so that the matter or fume deposited may be removed without suspending or impeding the working of the furnaces. For this purpose the incombustible material is contained in an iron framework or crate, made of the same height and width as the culvert which leads to the chimney, and the culvert is arranged so that the framework can be readily introduced into and removed from it. By this means, when the framework is filled with incombustible material, and is inserted in the culvert, the current of gases from the furnace must pass through the interstices between the material in it. The culvert is, by preference, arranged so that two or more frameworks may be introduced into it, in order that before removing one framework from the culvert another one may be introduced into it. They also propose to prevent the escape of smoke from engine and other furnaces where coal is used, by retaining the solid particles which escape from the chimney constituting what is commonly called smoke. *Patent abandoned.*

PROVISIONAL PROTECTIONS.

Dated July 8, 1863.

1698. T. Preece, Leominster, implement maker. An improved corn and seed drill.

Dated August 4, 1863.

1918. C. Gouty, La Tour, France, fuller. Improvements in fulling, thickening, felting, and cleansing cloths, and in apparatus connected therewith.

Dated October 6, 1863.

2444. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in steam boilers and furnaces. (A communication.)

Dated October 7, 1863.

2448. E. Jones, Gorton, near Manchester, engineer. Improvements in apparatus to be used for pumping water out of mines and other places.

Dated October 10, 1863.

2489. D. Proudfoot, Glasgow, drysalter. Improvements in printing or dyeing textile fabrics.

2490. J. W. Goundry, Old Shildon, Durham. Improvements in musical instruments.

Dated October 16, 1863.

2532. E. Rowing, Norwich, engineer. Improvements in steam engines and boilers.

2535. F. G. Stuber, 20, Waterloo-road, teacher. Improvements in lamps and stoves for the application of blast heat to horticultural, agricultural, and other specified purposes.

Dated October 17, 1863.

2549. E. H. C. Monckton, Cavendish Club, Regent-street. Improvements in the means of uniting or joining plates or sheets of metal, which invention is applicable to the construction of boilers, tubes, and other useful purposes.

Dated October 19, 1863.

2553. H. Gilbee, 4, South-street, Finsbury, London. An improved composition for rendering boots and shoes and other similar articles waterproof. (A communication.)

2556. J. Whitley, Leeds, brass and iron founder. Improvements in the permanent way of railways.

Dated October 20, 1863.

2562. C. T. Morley, Birmingham, stationer. Causing a more complete combustion of gas in using it for lighting purposes.

2567. H. Hennessy, Wynnefield, Charleville-road, Dublin. An improvement in projectiles.

Dated October 21, 1863.

2581. C. Schiele, Clarence-buildings, Manchester, engineer. Improvements in governors.

2584. T. Hodson, Preston, mechanic, W. Nightingale, Preston, factory operative, and R. Laird, Preston, mechanic. Improvements in machinery for carding cotton and other fibrous materials.

2587. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in treating ligneous substances in separating and recovering the fibrous portions therefrom, in preparing, bleaching, and sizing the same, and in machinery employed therein. (A communication.)

Dated October 22, 1863.

2592. G. Cutler, jun., 8, Wharf, Wenlock-road, City-road. Improvements in boilers and apparatus used for the generation of steam.

2593. R. Bailie, London-yard, Isle of Dogs, iron ship builder. Improvements in the construction of floating docks.

2594. H. Wilson, Stockton-upon-Tees, Durham. An improved lubricator for steam engines.

2596. A. A. Croll, Coleman-street, London, engineer. Improvements in the preparation of matters to be employed as disinfectants.

2597. C. Tusnot, Chaussée de Waterloo, 121, St. Gilles-lez-Bruxelles, manufacturer. Certain improvements in the manufacture of cartridge bottoms or entire cartridges composed entirely of the same elements.

2600. J. Mitchell, Dyke-head, Lanark, gentleman. Improvements in sinking, quarrying, and excavating in the earth.

2601. C. Parker, Dundee, Forfar, machinist. Improvements in machinery or apparatus for winding yarns or threads.

2605. C. J. Pownall, Jermyn-street, Westminster. Improvements in preparing and cleansing vegetable fibres, and in machinery employed therein.

2606. W. W. Burdon, Newcastle-upon-Tyne, esq. Improvements in reducing and preparing wood for the manufacture of paper and pulp.

2607. R. A. Brooman, 166, Fleet-street, patent agent. A new material for tanning. (A communication.)

2608. H. Bridson, Bolton, bleacher, and J. Alcock, millwright. Improvements in machinery for plaiting or folding fabrics.

2609. T. Dickins, A. L. Dickins, and H. Heywood, Middleton, Lancashire, silk dyers. Improvements in dyeing threads of silk.

2610. A. Turner, Leicester, elastic web manufacturer. Improvements in looms for weaving.

Dated October 23, 1863.

2613. M. A. Boyle, Claremont-house, Holland-street, Kensington. Improvements in portable writing cases and despatch cases.

2615. J. Claes, 18, Rue de l'Echiquier, Paris, patent agent. An improved apparatus for regulating the emission of gas. (A communication.)

2616. J. T. Webster, Mansfield, Nottingham. Improvements in driving the spindles of doubling and spinning frames.

2618. V. J. Cassaignes, 35, Rue de Rivoli, Paris. Improvements in the manufacture of the prisms, lenses, and glasses of stereoscopes, and in ornamenting glass.

2620. J. Parker, 6, Lilford-road, Camberwell, gentleman. Improvements in the application of steam combined with air as a motive power, and for other purposes.

2621. A. V. Newton, 66, Chancery-lane, mechanical draughtsman. An improved mode of manufacturing railway wheels. (A communication.)

Dated October 24, 1863.

2623. W. Betts, Wharf-road, City-road, capsule manufacturer. Improvements in the manufacture of metallic capsules for bottles and similar vessels, and in the apparatus or means for applying or fixing such capsules thereon.

2624. E. S. Crease, Tavistock, Devonshire, mining engineer. Improvements in machinery for drilling, boring, or excavating rock or other earthy substances.

2625. J. Davidson, Leek, Staffordshire, silk manufacturer. Improvements in doubling yarns or threads of silk and other fibrous substances, and in the machinery employed therein.

2626. J. Thomas, 5a, Great Bolton-street, Kennington-park, gas meter indicator maker. Improvements in gas meter indicators.

2627. G. Haseltine, 12, Southampton-buildings, Chancery-lane, civil engineer. A new attachment to coverings for the head, and to other articles of dress, for lighting matches. (A communication.)

2628. F. B. Baker, Sherwood-street, Nottingham. Improvements in apparatus used in dressing lace and other textile fabrics, and suitable also to the application of dyes or colouring matters thereto.

2629. J. Brown, 27, Aldgate, J. T. Way and T. M. Evans, 106, Leadenhall-street. Improvements in preparing cements and varnishes.

2631. L. J. Hannart, Brussels, Belgium. An improved clasp or fastening for gloves or other wearing apparel, for umbrellas, travelling bags, or other similar objects.

2633. A. Sellar, Reading. An improved instrument for lubricating rifles and other descriptions of firearms, also ordnance.

2635. A. Alison, 72, Sloane-street, Chelsea, gentleman. Improvements in atmospheric railways, and in carriages for the same.

Dated October 26, 1863.

2637. B. Steinmetz, 97, Rue Notre Dame des Champs, Paris. Improvements in locks for bags.

2639. T. Marsh, Sheffield. Improvements in projectiles.

2641. M. Vian, Marseilles, shipbuilder. Certain compositions for preserving iron ships and other submerged iron work from corrosion and decay.

2643. W. E. Gedge, 11, Wellington-street, Strand. An improved pillow. (A communication.)

2645. J. Willcox, 1, Ludgate-hill, London, sewing machine manufacturer. Improvements in sewing machines. (A communication.)

2647. E. Clifton, ironmonger, and B. Greenwood, brush manufacturer, Manningham, Bradford, Yorkshire. Improvements in the manufacture of brushes used in machinery employed for preparing and combing wool, cotton, silk, and other fibrous substances.

Dated October 27, 1863.

2649. T. H. Holderness, Liverpool, merchant. Improvements in propelling navigable vessels.

2651. T. Grason, Manchester, merchant. Certain improvements in boots, shoes, clogs, and such like coverings for the feet.

2653. W. Livingstone, 51, Glengall-road, Poplar, engineer. An improved machine for punching, shearing, and rivetting metals.

2655. P. B. O'Neill, Warwick-street, Regent-street, gentleman. An improved salinometer, which is applicable also as a hydrometer, and for other similar or analogous purposes.

2657. E. R. Hollands, 16, Charles-street, Northampton-square, machinist. Improvements in machinery for punching, cutting, and pressing metals and other materials.

2659. W. Firth, Burley, Leeds, merchant, S. Firth, gentleman, and J. Sturgeon, consulting engineer. Improvements in machinery for cutting and boring coal, stone, or other minerals.

Dated October 28, 1863.

2661. J. Marshall, Stockport, Chester, cotton spinner. Certain improvements in apparatus for applying adhesive substances to spindles employed in spinning cotton and other fibrous materials and for the lubrication thereof.

2667. R. Needham, Dukinfield, Cheshire, and J. Pollitt, Heywood, Lancashire, engineers. Improved equilibrium valves for steam engines and other purposes.

2669. M. Henry, 84, Fleet-street. An improvement in, or addition to, military knapsacks, travelling bags, and other similar articles. (A communication.)

2675. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in clocks, watches, and other timekeepers. (A communication.)

PATENT APPLIED FOR WITH COMPLETE SPECIFICATION.

Dated October 28, 1863.

2663. W. E. Gedge, 11, Wellington-street, Strand. An improved system of permanent advertisement. (A communication.)

NOTICES OF INTENTION TO PROCEED WITH PATENTS.

From the *London Gazette*, November 10, 1863.

1525. J. G. Jennings and M. L. J. Lavater. Stoppers.
1628. A. K. Richards. Ordnance and firearms.
1633. J. Blake. Apparatus for reducing and regulating the pressure or quantity of steam.
1653. W. Snell. Waterproof material. (A communication.)
1636. T. Boyle. Ventilation.
1637. C. P. Coles. Apparatus for working guns.
1645. J. J. Shedlock. Wet gas meters.
1652. C. Martin. Materials for the manufacture of paper.
1653. H. Broadhead and G. Murdoch. Breech-loading ordnance.
1654. W. E. Newton. Skins. (A communication.)
1655. R. Davison. Cleaning corn. (A communication.)
1662. M. E. Eyth. Rotative engine.
1663. J. McDonald. Jacquard looms.
1671. G. A. and A. Barrett, W. Exall, J. Andrewes, and J. L. Bowhay. Thrashing machines.
1680. G. C. Collyer. Cut tobacco.
1685. G. Bartholomew. Shoes.
1699. A. G. Southby. Diverse lamps.
1723. C. de Bergue. Piles for foundations.
1736. J. Orr, J. Brinton, and J. Lewis. Weaving "chenille."
1739. H. Greaves. Railways and tramways.
1744. H. N. King. Producing spectral illusions on the stage.
1784. L. R. Bodmer. New product from peat. (A communication.)
1787. J. Lamb and S. Tovey. Looms.
1802. J. H. Johnson. Machine knitting-needles. (A communication.)
1843. M. A. Soul. Expelling solid and liquid refuse matter from steam and sailing ships. (A communication.)
1848. W. Clark. Saddles. (A communication.)
1888. W. and S. Firth. Apparatus for working coal and other mines.
1989. L. R. Bodmer. Dressing and finishing yarn. (A communication.)
2050. A. Cruickshank. Food for cattle.
2140. F. C. P. Hoffmann. Shears.
2145. G. Attack. Bearing springs.
2176. W. Boulton and J. Worthington. Encaustic tiles.
2207. J. Burch. Printing on certain and other terry and velvet pile carpets.
2220. E. T. Hughes. Chenille. (A communication.)
2347. A. Collingridge. Casks.
2352. T. and W. Marshall. Metallic instruments.
2393. J. Chidley. Bottle and stopper.
2515. J. Rowley. Fibrous materials.
2549. E. H. C. Monckton. Joining plates.
2574. G. H. Daglish and T. Windus. Bending plates for iron ships.
2583. G. Howell. Condensing metallic and other fumes.
2588. Z. Colburn. Steam engines.
2593. R. Baillie. Floating docks.
2661. J. Marshall. Adhesive substances to spindles.
2728. J. Tangye. Shearing and rivetting machines.

The full titles of the patents in the above lists can be ascertained by referring back to their numbers in the list of provisional protections previously published.

Opposition can be entered to the granting of a patent to any of the parties in the above list who have given notice of their intention to proceed, within twenty-one days from the date of the *Gazette* in which the notice appears, by leaving at the Commissioners' office particulars in writing of the objection to the application.

LIST OF SEALED PATENTS.

Sealed November 6, 1863.

1177. B. Hargreaves.
1178. R. Burgess.
1183. R. A. Brooman.
1186. J. E. McConnell and G. H. Bovill.
1191. J. E. McConnell and G. H. Bovill.
1192. W. Whiteley.
1210. T. Lawrence.
1241. W. Watson.
1270. W. Walker.
1272. W. Nunn.
1248. C. Barnard, J. Bishop, C. Barnard, jun., and G. Barnard.
1280. J. Goodman.
1293. E. Barlow, J. Ashworth, J. Newhouse, F. Hamilton, and W. Hope.
1309. H. A. Bonneville.
2087. L. E. C. Martin.
2132. H. W. Putnam.
2144. L. E. C. Martin.

Sealed November 10, 1863.

1189. T. Warren.
1195. R. A. Brooman.
1197. R. A. Brooman.
1199. R. A. Brooman.
1203. J. E. McConnell and G. H. Bovill.
1208. J. Farmer.
1209. R. A. Brooman.
1212. A. Pilbeam.
1219. I. Parker.
1220. B. Shillito and D. Moor.
1222. D. M. Fyfe.
1224. A. Macmillan.
1225. R. T. Mallet.
1226. J. Patterson.
1229. B. Browne.
1232. F. M. Burns.
1235. J. Gibbs.
1236. W. White.
1238. E. B. Wilson.
1239. J. Whitehead.
1269. G. R. Harding.
1275. N. J. Amies.
1277. W. H. Clapp.
1278. E. Sonstadt.
1306. J. Hesford.
1307. W. Muir.
1320. W. Clark.
1326. F. W. and J. Kitson.
1332. H. J. Kennard.
1341. C. F. Baxter.
1362. W. Clark.
1431. C. Nicquet.
1485. J. S. Benson and D. Jones.
1499. W. Clark.
1522. A. Samuelson.
1899. A. R. Arrott.
2128. J. Alison.
2142. A. Rowand.
2188. G. Hargreaves.
2239. T. J. Sloan.

PATENTS ON WHICH THE STAMP DUTY OF £50 HAS BEEN PAID.

2983. R. Harrison and G. Taylor.
2763. W. Spence.
2788. R. W. and J. Waithman.
2815. J. Stockley.
2725. C. Asprey.
2728. J. Higgins and T. S. Whitworth.
2800. J. Crooke.
2742. A. J. Sedley.
2826. G. Glover.
2760. J. W. Wallis.

PATENTS ON WHICH THE STAMP DUTY OF £100 HAS BEEN PAID.

2585. H. Bessemer.
2593. W. Weild.
2639. H. Bessemer.
2596. C. Titterton.
2642. F. J. Manceaux and E. N. Vieillard.

THE MECHANICS' MAGAZINE.

Contents of the Last Number:— Page

THE
MECHANICS' MAGAZINE.

LONDON, FRIDAY, NOVEMBER 20, 1863.

BESSEMER SCRAP AND ITS USES.

The art of welding steel in large masses still constitutes the *pons asinorum* of the ironmaster. By the aid of the magnificent machinery of the present day, we can twist, turn, knot, shear, and punch colossal bars and plates of iron with as much ease as the baker works his dough; yet the process of welding remains as difficult, uncertain, and troublesome as though the excogitations of the inventor had never been devoted to the subject. It is true that steel is welded daily; that it will punch and flange like copper, yet sustain a strain of 120,000 lbs. per square inch; but the materials which permit of such manipulation partake more of the kindly nature of iron, than of that stubborn determination to break rather than bend, which is so uniformly associated in the mind with the term steel. It is not, perhaps, easy to say where we are to draw the line of demarcation, or to define exactly what is iron and what is not. The degree of carbonization will scarcely settle the question; for the quantity of carbon necessary to bestow a share of the qualities of steel on iron, may vary with different samples in a very remarkable degree. This much we do know: cast iron will not weld, be it ever so pure, and free from silica, phosphorous, sulphur, or any other of those foreign substances which it is the object of the manufacturer to eliminate; and the more nearly any sample of wrought iron, steel, or homogeneous metal, resembles the pig, the more unlikely is it that it will possess those welding qualities which would so materially enhance its value. To judge by the records of the Patent-office, any improvement in this department of the iron manufacture has been generally regarded as hopeless, until recently. Few and far between are the specifications as it is, which detail "improvements in the process of welding steel;" yet any one, acquainted with the nature and magnitude of the demands made daily on the skill of the smith, would see that it is from no want of inducement, apparently, that there has been a dearth of labourers in this field for invention. The world wants a thousand things made of steel, which it must continue to want, until we can contrive the means by which the stubborn metal can be welded with the ease and certainty of wrought iron. When shall we have cast steel faces welded on our armour plates? When will steel cables be supplied to our ships? When will incompressible steel top flanges be welded comfortably on to our deck beams and bridge girders? Built-up steel guns, we have got, perhaps as a first instalment; and we regard them as prophetical of the steel armour plates, cables, anchors, and girders, which are sure to follow ere long.

Meanwhile, Mr. Bessemer's magnificent process is said to be open to a serious objection. Good as his metal is, it is asserted that the scrap from it is useless, that it cannot be re-welded, and that it will not re-melt or combine with facility with new metal in the converting vessel without deteriorating the quality of the entire charge. These are grave statements, and deserve at least careful consideration. The quantity of Bessemer scrap made annually at many works, must be measured by hundreds of tons; and even though the difficulties in the way of its re-working may not be sufficiently great to preclude its use altogether, they may be quite enough to render that re-working a very unprofitable undertaking. If such is really the case, the introduction of Mr. Bessemer's process into extended use would be materially retarded—a result very much to be deprecated. We confess that we cannot discover any rational foundation for the statement in an extended form; yet it is quite possible that the objection is urged in all good faith. The manufacture of Bessemer metal is not confined to one firm; and, in consequence, its quality is as varied as that of any other substance which is made to supply a demand. In other words, it may be had extremely good, or extremely bad. Certain samples have been compared, we do not doubt justly, to refined pig iron. These, of course, will neither ball nor weld in the hands of the smith; but it is absurd to make a sweeping assertion on the faith of the deductions drawn from such premises. We have seen plenty of bad scrap wrought iron ere now, which could scarcely be welded in the first instance, or made available for anything but the commonest purposes subsequently. Yet no one condemns wrought iron scrap generally, because a few particular cases of the nature stated, are met with now and then. It is not easy, perhaps, to define what "scrap" is. Some firms class waste pieces of iron of all dimensions under this head; and when these are very considerable, the mass is absolutely worthless from the difficulty of re-working it. Some months ago, we saw the intermediate shaft of one of the Holyhead mail boats lying in Messrs. Boulton and Watt's yard at Soho. A scarcely perceptible crack had led to its replacement by another. The vast size of the shaft effectually precluded its re-manufacture. It could not be cut up cold. It would never pay to heat and forge it. Nothing remained, save perhaps, to set it up on end in the earth as a foundation for the anvil block of a steam-hammer. Verily, "scrap" is often useless, although it never traced its origin to the converting vessel.

Mr. Bessemer has not permitted the aspersion on the character of his process to pass unnoticed. An able letter from his pen has appeared in the pages of a cotemporary, in which he informs us, not alone of what may be, but of what actually *is*, done with "Bessemer scrap." Alluding to the first and most obvious use of this material, he tells us "that all the Bessemer scrap steel made in one establishment during the last two years has been sold to cast-steel makers, who melt it in crucibles in the same way as practised by them in working up the ordinary scrap steel made by the old process." The very details indeed, of his own system, offer the simplest of all possible means for rendering scrap steel a marketable commodity. The crop end of bars and ingots, can in this way be re-manufactured without any appreciable amount of labour being expended in their re-conversion into ingots of any desired weight or form. When these scraps are of small size they are sometimes thrown cold into the converting vessel; in some cases as much as 2 cwt. of cold steel scrap being used with every ton of melted crude iron; these scraps become completely fused during the converting process, and thus form an addition to the weight of ingots, obtained without any increase in the labour, fuel, or engine power employed to produce them. It has, however, been found preferable to heat the scrap previous to putting it into the vessel, and in this way Mr. Bessemer informs us that large masses of steel, weighing from 5 cwt. to 7 cwt., have been perfectly fused in the converting vessel during the short space of time occupied in the conversion of a charge of crude iron. Did no other means of disposing of his chips and parings present itself to the ironmaster, here at least, is one which can be employed to good purpose.

Bessemer steel is worked up, however, in hundreds of situations, where the converting vessel and the melting-pot are not accessible, and other methods of manipulating scrap must be resorted to. The steam-hammer is nearly ubiquitous; and there is, apparently, no good reason why steel rail-ends, ingot crop, plate shearings, &c., should not be worked up into serviceable bars by its aid. Here we begin to tread on tender ground. The practicability of welding Bessemer scrap depends just as much on matters of detail, which are governed by general laws, as the working of any other description of steel. "The property of welding," says Truran, "belongs to all metals, whether cast or malleable, but is most apparent in iron. It is produced by the infusion of caloric, until the iron and metalloids of the entire mass are softened, and the surfaces to be united reduced to a semi-liquid state. The comparatively large quantity required to liquefy wrought iron, enables the softening and partial fusion to be successfully conducted. Cast iron and other metals may be united by fusion; but during the accession of caloric, owing to the lesser quantity required and the inferior melting temperature, only a momentary period elapses between the softening and complete liquefaction of the entire mass treated, and the rapidity with which it escapes, does not permit of the manipulation necessary to the effectual consolidation of the pieces." The amount, by which the entire quantity of heat necessary to fuse a certain sample of Bessemer metal is less than that which would be required to fuse a like quantity of wrought iron; and the difference between the melting points of the two metals, at once determines the difficulty of welding the former effectually. In other words, the more nearly such a sample approaches in its nature to the harder cast steels, the greater the obstacles to be encountered in working it under the hammer. It is quite possible that metal may be, and probably is, made under the Bessemer patent, which is little better than cast iron when heated, crumbling to pieces by the effects of percussion, though tough enough when cold. For such scrap as this there is at present nothing but the melting pot. But this is not a usual characteristic of the material in question; and even if it were, it is by no means certain that the failure of the welding process is not more due to the lack of inventive genius on the part of the ironmaster, than in the imperfections of the metal sought to be worked. It is quite possible that the hardest cast steel may yet be welded on a large scale, with ease and certainty, by the aid of properly contrived machinery. Certain it is, that we weld steels now which could not have been welded a little while since; and the march of improvement may yet supply us with the means of producing, with a facility not known at present, that combination of pressure with percussion, which seems best adapted to forming a perfect union between the half-fused surfaces. Every smith who has had much to do with the forging of steel tools, is well aware of how greatly his success depends on the nature of the blows struck in the first stage of the operation of welding; and we can very well understand why certain manufacturers have failed in welding particular samples of so-called Bessemer metal.

Fortunately, the material which is produced by the aid of the converting vessel and its tuyeres, partakes far more of the qualities of soft wrought iron, than of hard steel, when the crude metal is of proper quality, and the process carried out as it should be. It is not our

purpose at present to dwell on the merits of Bessemer metal; but that it can be welded under proper arrangements with the greatest facility, when it assumes those characteristics of a mild pure steel which it ought to possess, there can be no doubt whatever. One of Mr. Bessemer's licensees, writing to him, says: "I have been making a pair of railway axles by piling the ladle scrap; and we have made such a perfectly sound job of them, that I think I shall never again make axles in any other way." So long as he supplies himself with the proper material, it is more than probable that this gentleman can pursue the method he proposes with success. Much greater things than this have been done, however, in the way of piling scrap or crop end. The London and North-Western Railway Company, having on hand the crop ends taken from five hundred tons of Bessemer steel rails, proceeded to pile these in precisely the same manner as practised in piling scrap iron. These piles were made into flat slabs, and were afterwards used to form the top and bottom sides of other piles, composed of old iron railway bars, and were then rolled into new railway bars, having steel faces, and the central part of common iron. More than one hundred rails were thus made, and after many unsuccessful attempts to detach the steel, both by hardening in water and by other means, they were laid down for use upon the line. Here we have an instance not only of the welding of Bessemer steel scrap, but also of its perfect welding to ordinary wrought iron; and the simple fact that all these scraps resulted from five hundred tons of Bessemer steel, made by not less than five hundred consecutive repetitions of the converting process, is excellent evidence that the metal in question, of a uniform welding quality, can be made with certainty in the regular and ordinary way of trade.

V. P.

TURBINES.

The class of water-wheels, known by the general term "turbine," supplies us with, perhaps, the most practically perfect means to be met with in the arts of obtaining the highest results from given mechanical effects. To all intents and purposes, the turbine is if properly constructed, a perfect motor, capable not alone of working under all sorts of circumstances and under the most variable conditions, but of invariably giving out a high coefficient of useful effect as well. Perhaps invented, at all events first rendered effective and economical, by Fourneyron, in 1837, it has gradually worked its way into general favour solely by its own merits. It is not easy to say how many of them are at work in Great Britain at the present moment. Messrs. Williamson, Donkin, Schiele, the North Moor Foundry Company, and many other firms, have, we believe, full employment found them in their construction; while abroad their use is even more extended than it is here in the fatherland of the steam engine—the giant who will scarcely brook the presence of a competitor within his territorial domains. In France and Germany, the turbine enjoys great favour; the comparatively high price of fuel acting to some extent, as a bar to the habitual use of steam machinery. In America, the ordinary vertical water-wheel was exclusively employed—the breast-wheel being considered best—until 1844. In 1843, Mr. Elwood Morris communicated to the Journal of the Franklin Institute, a translation of Morin's experiments on turbines, which attracted considerable attention. The year after, Mr. Boyden, an engineer experienced in the manufacture of hydraulic machinery, designed and constructed a horizontal water-wheel for the Appleton Company's mill, near Lowell, in Massachusetts, which at once embodied several improvements on the Fourneyron arrangement, and may be regarded as the first instance of this application of water-power in the States. In 1846, the same gentleman constructed three turbines, of about 190-horse power each, on the same general principles; the particular design being somewhat modified and improved. It is said that the mean maximum effect of two of these was found by careful experiment, to equal 88 per cent. of the theoretical power due to the fall—a statement which, probably, contains a slight exaggeration. The general principles and mode of formation which distinguish the Fourneyron wheel are so well understood that it would be superfluous to dwell on them individually at length. The water, distributed in horizontal jets by peculiarly curved vanes or guides, issues from the circumference of an inner fixed wheel, composed of two discs kept apart by the guide plates, and passing through an outer annular wheel, fitted also with guides of a contrary curvature, puts it in motion; its interior periphery revolving as nearly as possible, in contact with the exterior periphery of the inner or guide wheel. This is the Fourneyron turbine in its simplest form. One of the most important improvements effected by Mr. Boyden, was the application of the "diffuser," almost universally adopted since. The invention is embodied in the formation of two large stationary discs without and around the wheel, the space between which at the inner periphery is very little greater than that between the crowns of the wheel at the part next to them. These discs curve apart and outward, so that the space at their exterior periphery is twice as great. The section through which the water passes in escaping from the wheel is thus enlarged in the ratio of one to four; hence its action should fall from 1 to 1-16th in the same distance, provided the wheel be submerged. The effect of this arrangement is to reduce the pressure on the escaping water, and thus increase the power as though the fall were increased. The theoretical gain to be derived by this arrangement is equal to about 5 per cent. on the whole power; though from one cause or another only 3 per cent. is usually realized. Mr. Boyden suspended his turbine from above, and was the first to point out the expediency of employing very thin guide-plates and vanes. One of the greatest objections to the Fourneyron wheel and its modifications is, that, being always submerged, it is, to some extent, inaccessible for repairs or examination. It is frequently far from convenient to drain away the water, especially when more than one turbine is supplied from the same race. As early as the year 1838 this objection was recognized, and the "Jonval" wheel introduced to obviate it. Instead of revolving outside the stationary guides, the buckets in this turbine revolve below them. Both the fixed and moveable wheels are placed within a tube of sufficient diameter, the orifice of which, placed below the level of the water in the lower race, is so contracted as to allow of only the proper quantity of water passing through, due to the velocity arising from the difference of the two levels above and below the turbine. By this arrangement the wheel may be placed in any part of the height of the fall deemed most desirable; the necessary force and velocity of the water being obtained by the pressure of the atmosphere on the upper surface of the suspended liquid column. When the supply of water is cut off by closing the upper sluices, the wheel is left high and dry for repairs, as the tube is usually large enough to afford ample space for a man to work in it with ease.

When the turbine is employed to render high falls available, the foot-step of the vertical spindle often gives much trouble, as well from the difficulty of lubricating it properly, as from the great weight which it has to sustain, and the high speed at which the shaft revolves. At St. Blasier, in the Black Forest, a wheel only 13 in. in diameter is put in motion by a column of water 354 ft. high. Whether all the pressure due to this vast height is rendered available or not, we cannot say. The wheel makes 2,200 revolutions per minute, driving 8,000 water spindles, with the necessary machinery for slubbing, roving, &c. Fifteen hundred revolutions per minute are by no means uncommon with larger wheels. Mr. Boyden, in America, and Mr. Mallett, in this country, cut the Gordian knot by hanging the revolving ring and its shaft, and all the weight of water upon it, from a ring of conical rollers above the pen-trough, running between two faced-up iron plates, the central toe or step being used merely as a steadier. When the foot-step is retained, the best practice is to form a cavity in the end of the shaft, which is fitted accurately to a hardened steel pin, projecting upwards, firmly fixed in the base of the wheel pit, on which the entire weight is sustained. The proper shape for this pin and its corresponding cavity has been made the subject of much mathematical disquisition. Oil is usually supplied through an aperture drilled up the centre of the pin, by a very small force-pump, put in motion by an eccentric on some slow running shaft in the mill above. In the great Fairmount Jonval turbines, intended to supply water to the city of Philadelphia, the central shafts are supported on stout cast-iron columns, bolted down to the iron bottom of the draft box or vertical tube. A socket resting on the top of this column contains a circular block of lignum vitæ, 15 in. in diameter and 8 in. or 9 in. thick. Its upper surface is rounded to a partially spherical shape, and a few spiral grooves are cut in its surface to permit the entrance of water, and thus secure constant lubrication. A cast-iron socket, hollowed out to fit this block, is keyed on the lower extremity of the vertical shaft, thus forming the bearing. These wheels are, perhaps, the largest of the kind in the world, being not less than 9 ft. in diameter over the buckets; each wheel, we believe, drives a nearly horizontal double-acting pump, 18 in. in diameter, and 6 ft. stroke, intended to make twelve double strokes per minute when pumping against the head of water in the reservoir.

The construction of the turbine suggests some of the most complicated problems in hydraulics, and theory scarcely yet affords the means of solving them. Practice alone supplies us with thoroughly trustworthy results. From this reason, there is little doubt that the statements of the usual effect realized from a given fall are frequently over-estimated. the quantity of water passing through the wheel being really in excess of that assumed from calculation. Still, making every allowance, there is no doubt that with proper care turbines usually give out a higher coefficient of useful effect than perhaps any other moving power in existence. At first sight, it appears that the entering water should impart a severe shock to the curved buckets which oppose its motion. This diappears, however, when the wheel moves at a proper velocity. Under correct arrangements, the water enters the wheel without impact, and passing along the

whole length of the blades which constitute the buckets, and exercising a pressure at every part, whereby its velocity is constantly reduced, while the direction of its motion is modified by their curve, it finally leaves the wheel with an insensible motion, being deposited as it were in the tail race, from which it flows in obedience to the law of gravitation at a velocity determined by the inclination of the floor on which rests. In order to secure this action, the most extreme accuracy of workmanship is absolutely essential. It is useless to set out the proper curves with a strictly mathematical precision, if these are afterwards departed from by an erroneous method of practical construction. Theoretically, the guide curves should have no thickness; and although this desideratum is unattainable, we can, at all events, approach almost indefinitely near to it. It is not easy to secure the necessary accuracy of fitting through all the details, by hand labour. The more extended use of machine tools specially designed to carry out the end in view, and of cast steel as a material of construction, may do much to reduce the first cost and improve the performance of the turbine; the latter imparting that stiffness and strength which cannot be obtained from the use of sheet-iron. It is impossible to over-estimate the importance of correct form, and it requires little reflection to show how easily thin guide plates may be deflected by the pressure of the water when the wheel is at work, although, when at rest, their shape may leave nothing to be desired. Machine tools would rapidly and cheaply impart that smoothness of surface and delicately beautiful curvature to the guide plate and buckets, on which the efficiency of the machine almost wholly depends.

THE ORDNANCE REPORT, 1863, CONDENSED; AND CONCLUSIONS FROM IT.*

No. II.

In the first part of our analysis, a plain narrative of events, in the order of the dates, proved the exceptional position and commanding influence of Sir W. Armstrong in the War Department, from the beginning to the end of his career. By the same process we will, from the evidence, show the composition of the company formed by him, and its preferential position over all other manufacturers of ordnance.

THE ELSWICK COMPANY AND ITS COMPETITORS.

The Elswick Ordnance Company was the creation of Sir W. Armstrong. His name does not appear as one of the partners in the contract with the War Department, which is printed *in extenso* in the Appendix, but his personal interest was identified with it. This it would be idle to affect to doubt. The company was formed for his purposes and to carry out his views. Whilst he was in the service of the Government, at a salary of £2,000 a-year, the company's works were under his control. He was at the same time engineer of rifled ordnance at Woolwich and director at Elswick. The Government guarantees, beginning with £12,000 to Mr. Armstrong, and ending with £85,000 to the company, furnished the capital. The form of the guarantee is a masterpiece of ingenious contrivance. It was framed by an astute mind learned in the law. It provided, in the most stringent manner, that the company should incur no loss to the extent of the sum guaranteed by their expenditure on land, buildings, and machinery. With such a guarantee, and such a guarantor, double the largest sum named could be, and in fact was, readily obtained on easy terms. The secured capital invested in this promising undertaking amounted to £168,000. This amount, be it observed, was the fixed capital. The floating or trading capital, looking at the vast extent of the transactions, probably was at least as much more; we shall, no doubt, be within the mark in setting the gross capital down at £300,000. The firm "slept on velvet;" there could be no loss; full employment of the works was guaranteed, and there was no limitation to the prices to be charged.

Doubtless it was the privilege of the author of the scheme to nominate the lucky partners. We learn from the Report the names of some of those gentlemen—they are Mr. George Cruddas, Mr. Richard Lambert, Mr. George W. Rendel, and Capt. Andrew Noble, R.A. Of the two last named, the first—a son of the late Mr. Rendel, the celebrated engineer—was brought up under the guardianship of Mr. Isambard Brunel, the brother-in-law of Sir Benjamin Hawes, the Under-Secretary of War; and the latter was Secretary of the two War-office Committees, on whose reports the Armstrong ordnance, of every calibre, was adopted into the military and naval service of Her Majesty. If there are other members of the firm, their names are not disclosed. We may, however, considering the large capital involved, reasonably conclude there are sleeping partners. Mr. Rendel and Capt. Noble were both young men; neither of them had any commercial experience before undertaking the management of the Elswick Company. We leave the public to form their opinion of the coincidence, which made the Secretary of two Committees which reported in favour of the Armstrong ordnance, and a family connexion of a high official of the War-Office, co-partners of the fortunate projector, and instruments to carry his plans into effect. When we come to the cost of the Elswick guns and projectiles, we shall find the prices paid for them were on the most liberal scale, considerably higher than the cost of the same articles at the Woolwich factory.

We have shown from the evidence how, by a series of events, the Armstrong party obtained a position to command success. We say *party*, because it clearly results from the evidence that a number of persons were engaged, and had a common interest with Sir W. Armstrong in carrying out his views. We proceed to point out by what means success was insured and competitors were kept aloof or frustrated.

At his *debût*, in 1854, Mr. Armstrong at once obtained an order from the Duke of Newcastle for six guns. This means three things invaluable to an inventor—a fair or rather an indulged trial of his invention; the patronage of Government; the expenses paid from the public purse. These advantages were in vain sought for by other projectors. The successive proposals of Mr., and afterwards Sir, W. Armstrong, during five years, met with the same exceptional success, with reference to the three essential points, and gave him an immense superiority over all other artillery inventors.

They had to work their weary way up the official mountain and encounter rebuffs at every stage, whilst the road was made smooth to Messrs. Armstrong and Co. In July, 1855, the trial of the first gun met with qualified success; soon afterwards it was re-bored and again tried, and another gun was ordered. To suit the convenience of Mr. Armstrong, who was absent on the Continent, the trial was delayed some months. These preliminary experiments were of great value to the inventor; he was enabled to correct his errors, and modify his plans, continually favoured with the cordial co-operation of the Ordnance officials. At the beginning of 1858, it is clear from the evidence, that the arrangements then made were destined to give to the future Sir W. Armstrong, that preponderance of preparedness, requiring much time and careful combinations, which should enable him to distance all competitors at the trials, which were to determine the adoption of a system of rifled ordnance for the two services.

After carefully going through the correspondence and reports, from January, 1858, to January, 1859, and comparing the incidents recorded in the Ordnance Report during that eventful twelvemonth, we are painfully impressed with the conviction, that Sir William Armstrong and his friends were in the secret; whilst all other artillerists, who might, and many of whom would, have been competitors, were in profound ignorance of the nature of the trials, which were to take place so soon as the Armstrong preparations were completed. Between February and April, 1858, Mr. Armstrong received from the Ordnance authorities the orders for the guns and projectiles, which, towards the close of that year, were used in the so-called competitive experiments. When the time came, he was fully prepared with guns of different kinds, calibres, and projectiles of every denomination. So much were all other projectors taken by surprise, that Mr. Whitworth was the only one who entered the lists, and he had not at the time the most remote idea of what was really intended. It might be supposed we are over-stating the case, so incredible does the proceeding appear; but we will leave the facts furnished by the Report to speak for themselves.

To elucidate the true state of the case, we call attention to the appointment, in September, 1858, of the "Special Committee on Rifled Cannon," of which Colonel Mitchell was president, and Captain A. Noble, secretary. Some weeks previously, there was note of preparation, in the War Department, for the coming decision, by "General Peel calling on Colonel Lefroy, the President of the 'Ordnance Select Committee,' to report on all the experiments that had been tried on rifled ordnance."

In a letter to Colonel Mitchell, dated the 8th September, 1858 (Appendix, p. 399), he is informed, *by order of General Peel*, that the Committee is appointed "to consider and report upon the best form of rifled cannon for adoption in Her Majesty's service, as well as of the projectile to be used with it; to ascertain the best pattern of rifled gun for garrison and for field service; likewise to ascertain whether there be now in existence any pattern or patterns of rifled cannon fit for adoption into the service;—the paramount importance of arriving at a speedy decision on those questions" is pointed out, and the Committee are "empowered immediately to proceed to experiments as they may consider necessary." In this despatch the Armstrong system, although not mentioned, was, doubtless, in the "mind's eye" of the Secretary of State. It was well known in the Ordnance *bureaux* that no other artillery projector was in such a state of preparation, as to admit of the immediate adoption of his plan, or even to give him the chance of competition with Sir W. Armstrong; General Peel's decision,

* ERRATA in No. 1 of the Condensed Report, pp. 784, 785.—3rd column, for "Col. Lessing," read "Col. Lefroy." 3rd and 4th columns, for "1848," read "1858;" for "Col. George," read "St. George." 4th column, two sections commencing "In October, 1859" and "4th Nov., 1859," should precede the section commencing "This Naval Gun." 5th column, for "contemptousness," read "contemptuous."

therefore, on this matter was simply a prelude, in form, for the adoption of the favoured system. He himself, and the Ordnance officials, were well aware that there was no competitor prepared to oppose Sir W. Armstrong, who could not fail to walk over the course.

All this at the time was known only to the initiated. Neither in the title of the Rifled Cannon Committee, nor in any public or private notice, did anything appear to lead artillerists to suppose that the object of that Committee was to "test the strength of guns and their capabilities to fire various projectiles," or "to come to a speedy decision on the best form of rifled cannon for adoption for garrison or for field service." So little did many of them anticipate decisive trials of that nature, that they were wondering that their plans for those purposes, which had been proposed to the Government some years ago, had not been submitted to experiment. There can be no doubt, looking at his intimate official relations at that time, Sir William Armstrong was fully cognizant of the nature of the proposed proceedings, and took his measures accordingly. He knew that that Committee was appointed to determine, principally and forthwith, what system of field guns should be adopted to the exclusion of all others. The evidence of all the other projectors, who had, during the preceding three or four years, submitted proposals to the War-office, proves they were misled and mystified, not having had the same opportunities, as Sir W. Armstrong, of knowing what was really intended. Those who knew anything supposed that the only question to be determined by the Rifle Committee was the *best system of rifling ordnance.*

The proceedings which threw off all candidates for Ordnance contracts, except Sir W. Armstrong, were thus conducted :—Inventors were invited to adopt their modes of rifling and strengthening cannon to cast iron guns, on the ground of the importance of utilizing the immense stores of that description of ordnance in the Royal Arsenals. A number of distinguished artillerists, comprising Commander Scott, R.N., Mr. Lancaster, Mr. Whitworth, Mr. Bashley Britten, and Mr. Lynall Thomas preferred their claims. Sir W. Armstrong entered the lists with his "shunt," the lead-coated compression system not being applicable to muzzle-loaders. Several 68-pounder and 32-pounder cast-iron guns were strengthened and rifled on the various plans proposed. Considerable delay took place before the experiments were completed and reported. Dates here are important. This scheme of competition, which looked fair and reasonable, commenced in 1857 and 1858; the results were not realized till 1860. In the meantime Sir W. Armstrong alone, practically, had the privilege of submitting *wrought-iron* rifled guns to be experimented upon at the public expense; and this he did, with the favour and indulgence before described. Every competitor but himself looked to the trial of his plan of rifling is applied to those cast-iron guns, and when the result of the competition was made known, they learnt with amazement that the whole question was decided by the experiments with the Armstrong built-up guns, in which they had no opportunity of participating.

In support of this view of the case, we now quote the evidence from the Report. Appendix No. 62, p. 546, dated War-Office, 27th June, 1863, is a "Return of strengthened Cast Iron Guns (some Rifled) which have been tested in Experiments by the Ordnance Select Committee since the year 1858." It gives the particulars of the trials of 20 guns, of which it will suffice to detail the results of three guns, which in the return take the highest and lowest places, as determined by the number of rounds fired before the guns burst.

Names of Artillerists.	Nature of Gun.	Weight of shot. lbs.	Weight of charge. lbs.	Number of Rounds.
No. 1, Bashley Britten and Blakely	32 pr. rifled	... 67½	... 8	... 133
No. 2, do. ...	32 ,, ,,	... 48	... 5	... 84
No. 3, Lancaster...	32 ,, smooth-bore	32	... 10	... 81
No. 16, Captain Caffin, R.N., Director of Stores.........	32 ,, ,,	... 35	... 16	... 22
No. 17, Armstrong shunt	68 ,, rifled	... 80	... 18	... 12
No. 18, do. ...	68 ,, ,,	... 90	... 13	... 4

The Bashley Britten system of rifling, combined with the Blakely plan of strengthening, stands pre-eminently at the head; the Lancaster takes an honourable second rank; the Ordnance candidates are at the bottom of the list, the Armstrong "shunt" being the most inefficient of all the plans of rifling. These were the results with cast-iron guns; but they are *comparative*, they prove the superiority of the Britten and Blakely systems over the Armstrong, and leave no doubt that the same superiority would be maintained in wrought-iron guns. Nevertheless, Sir W. Armstrong, with his usual good fortune, has had a number of wrought-iron guns, of large calibre, made at the public expense on the shunt principle, and received the aid of the War Department to introduce them into the service as naval and siege guns. On the other hand, Mr. Bashley Britten and Captain Blakely have, in vain, made reiterated attempts to obtain the privilege of having even a single gun on their principle experimented upon. The gallant officer's proposal to supply a heavy gun at his own expense was refused.

(*To be continued.*)

INSTITUTION OF CIVIL ENGINEERS.

November 10, 1863.

JOHN HAWKSHAW, Esq., President, in the Chair.

THE Paper read was "Description of Lighthouses lately erected in the Red Sea," by Mr. W. Parkes, M. Inst. C.E.

Having been instructed by the Board of Trade to make the necessary preliminary surveys for establishing lights to facilitate the navigation of the northern portion of the Red Sea, the author recommended three sites—1st, Zafarana Point on the Egyptian shore, 50 miles from Suez; 2nd, the Ushruffee Reef, on the western side of the navigable channel of the Straits of Jubal, 150 miles from Suez; and 3rd, the Dædalus Reef, in the centre of the Red Sea, 350 miles from Suez, and 180 miles from the entrance of the Gulf of Suez. These sites having been approved by the Egyptian Government, by the Board of Trade, and by the directors of the Peninsular and Oriental Steam Packet Company, the immediate execution of the works was authorized upon designs submitted by the author.

Zafarana Point being on the mainland, it was considered most advantageous to construct a tower and lightkeepers' dwellings of rubble stone, and to employ native labour entirely, under the direction of H. E. Linant Bey, the chief engineer of the Public Works Department of the Egyptian Government. The design presented no feature calling for special remark, and the works had been carried on in a very satisfactory manner. The light was a fixed dioptric of the first order, visible over five-eighths of a circle at a distance of fourteen miles. It was first exhibited on the 1st January, 1862.

The main features of the other sites were then described. The Ushruffee was a coral reef, of which the sides sloped irregularly from the level of a few inches under low water to a depth of from eight to ten fathoms, no part being above the water, and there being very little sand, even in the cavities of the coral. The Dædalus Reef was a submerged island, with a flat top of an oval form, 1,200 yards in length and 450 yards in breadth, the sides being generally vertical, or in some places even overhanging. The actual surface of the coral was about 6 in. under low water; but there was a small shifting bank of sand near the south-east end which was dry at low water, and sometimes also to a small extent at high water. The range of tide was about 2 ft. at springs.

The peculiar conditions which had to be considered in designing the proposed constructions were—first, the force of the sea would be completely broken at some distance within the edge of the reef; secondly, the structures would have to be built upon the surface of the reef, and not be sunk into it, as no additional security could thus be obtained, while the advantage of the natural platform would be lost; thirdly, in the absence of any definite experience as to the actual weight which the reefs would bear without being crushed, it was desirable to keep the weight per superficial foot of foundation as low as possible; fourthly, the buildings had to be designed so as to mitigate the intense summer heat; and fifthly, in the case of the Dædalus, as the materials would have to be brought from Suez, and, as there was no anchorage, it was necessary that a steamer should be employed capable of keeping close to the reef in any wind, and of providing quarters for the workmen and storage room for the materials, until a proper depot and habitation could be formed on the reef itself. These requirements rendered it essential that the materials should be small in bulk, that the several parts should be light and easily handled, and that the mode of putting them together should be as simple as possible.

It appeared to the author that these conditions would be best attained by adopting a structure of wrought iron supported on teak piles, resting on, and the feet bedded in, a layer of concrete, so as to distribute the weight, the surface of the concrete being a little above the level of high water; and that, by filling in the wrought-iron framework with strong corrugated iron, so as to form a series of rooms one above the other, as a central column, with verandahs or galleries around each room, likewise partially enclosed, a portion, at least, of the sun's rays would be prevented from falling on the walls of the rooms, while there would be a free admission of air.

As the Dædalus light had only to guard against the dangers of the reef on which it was placed, it was not necessary that that structure should exceed the limited height that would allow of four tiers of rooms, and of accommodation for the lighting arrangements. These together brought the light to an elevation of 62 ft. above the mean level of the sea. As the Ushruffee light had to lead vessels past dangers twelve or fourteen miles distant, a more powerful light, at a greater elevation, was required. The height fixed upon was 125 ft. above the mean level of the sea. The framework was of the same description in both cases; but in the latter case there were eleven tiers, whereas in the Dædalus there were only four tiers. Details were then given of the Ushruffee structure, as being the larger of the two. It was stated that this structure was supported upon eighteen piles, each 18 ft. long and 18 in. diameter, arranged in two concentric circles. The inner circle consisted of six piles, and was 15 ft. diameter, while the outer circle was formed of six pairs of piles (the piles of each pair being 6 ft. apart), 37 ft. diameter at the top, and the feet spread outwards at a batter of 1 in 12. The feet of the piles rested upon the natural surface, and there were shoulders on each side of the piles resting on sleepers of teak, bedded on the concrete 3 ft. to 3 ft. above the surface of the coral. The heads of the piles passed through circular wrought iron collars, to which they were accurately fitted, and any loosening by the shrinkage of the timber, was provided for by fitting a number of wedges of greenheart timber into corresponding grooves in the pile heads, in which they could be driven down when slack. A direct bearing surface was also given by iron screws, 2 in. diameter, which passed through each collar, and entered 2in. into the wood. The collars had projecting arms, to which the bottom framing was rivetted. The superstructure consisted of a repetition of three main parts, which might be called respectively, standards, sills, and radiators. In each tier there were twenty-four standards, arranged in two concentric circles, and these were connected at the top and bottom by sills, thus forming two twelve-sided polygons, the corresponding angles of which were connected by the radiators. With the exception of a few parts near the bottom, no separate piece exceeded 4 cwt. in weight. The floors of the rooms were composed of cast-iron plates covered with concrete, and from the lower floor there was suspended a hemispherical water tank, capable of holding 1,500 gallons. The floors of the galleries were formed of open cast-iron gratings. The whole of the ironwork of the stru-

ture was erected on Messrs. Forrester and Co.'s premises, at Liverpool, with the view of attaining the accurate fitting of the parts and of testing its strength. While at its full height, with the exception of the piles at the bottom and the lantern at the top, but with the joints merely bolted together, it was exposed, in September and October, 1860, to two gales of wind of the registered force, respectively, of 20·5 lbs. and 24·3 lbs. per square foot. There was no appearance of any straining of the joints, and a careful examination failed to discover any swaying movement at the top, though there was a sensible vibration. Since its erection on the reef it had been subjected to two severe gales, in June, 1862, and in January, 1863, with similar results; for, although the top of the building had vibrated, there were no symptoms of straining having occurred.

The general principles of the construction of the Dædalus lighthouse were the same as those of the Ushruffee, with such modifications as its smaller size demanded; thus there were only twelve, instead of eighteen piles, and the dimensions of the parts of the framework were the same as for the upper tiers of the Ushruffee. The building was stated to be very stiff, scarcely any vibration being perceptible under a strong breeze.

The lanterns were of the same construction for the three lighthouses. Those for the Ushruffee and Zafarana, being for first-order lights, were identical in every respect. That for the Dædalus, being for a second-order light, was of reduced size. In construction they were similar to those generally manufactured for the Trinity Corporation, but with special arrangements for mitigating the powerful effects of the sun. At the suggestion of Professor Farraday a wind-guard was substituted for the ordinary revolving vane and cowl. The lanterns and light apparatus were furnished by Messrs. Wilkins and Co., the optical portion having been manufactured by Messrs. Chance Brothers, whose improvements in lighthouse illuminations deserved special notice. The Zafarana and the Dædalus were fixed lights, while the Ushruffee had a revolving light frame.

The whole of the materials of the two iron lighthouses, and of the three lanterns and light apparatus, were, with some trifling exceptions, despatched from Liverpool within ten months from the date of the author receiving instructions to proceed to survey the sites, at a distance of nearly 3,000 miles from Great Britain.

As the structures were designed with a special view to the peculiar circumstances of the sites upon which they were to be erected, it was considered desirable to give some account of the operation of erection. The Peninsular and Oriental Steam Packet Company granted, gratuitously, the services of the "Union," a screw steamer of 300 tons and 60-horse power, the Egyptian Government paying for all wages, stores, and coal. The materials arrived at Alexandria on the 12th of November, 1860; but it was not until the 20th of December following that they were all received at Suez, and placed on board the "Union," which then sailed for the Ushruffee Reef. The expedition thus commenced was unfortunately not successful. The causes of the failure were given at length in the Paper; but it would be sufficient to state the results of the season's labour, which lasted three months. The piles were erected on the reef, and their heads were connected by the bottom iron frame. The whole of the ironwork was landed, and laid out in order upon one of the neighbouring islands. This was not originally intended, as the plan decided upon was to moor the ship as near as possible to the reef during the progress of the works, and to land and sort the materials upon the concrete base of the lighthouse itself. After a full inquiry into the circumstances which had led to this failure, the author was instructed to make arrangements for a new expedition, and he readily assented to the suggestion that he should remain on the spot until the operations, as to which difficulty had been anticipated, were completed. The permanent superintendence was entrusted to the late Mr. C. W. Scott (Assoc. Inst. C.E.), Captain W. Kirton being in command of the "Union." As the materials had been landed on the Ushruffee Island it was determined to form a land establishment for the working party there, rather than to quarter the men on board. This left the steamer free to carry a working party to the Dædalus, without interfering with the operations on the Ushruffee. The staff was re-organised, and the list of plant and of materials revised; but owing to several causes the operations were not resumed on the Ushruffee until the 8th November, 1861. The first step was to form the shore establishment. This occupied three weeks, owing to the want of skill of the native carpenters in getting the huts ready for occupation. During this time, however, some progress had been made at the lighthouse. The caisson of iron plates to enclose the concrete base had been set up, and about 200 tons of gravel had been placed upon the reef, where it was exposed to a wash sufficient to remove some of the clayey particles. The process of depositing the concrete was then commenced, the plan adopted being to deposit it upon sheets of tarpaulin, which sunk with the weight and protected the soft material from the action of the water, until a mass of several tons was collected. When the whole space was covered in this way up to above low-water mark, the remainder was deposited, as the state of the tide allowed, until the whole height of 5 ft. from the surface of the coral was complete. The first half of the concrete was formed of six measures of gravel to one of Portland cement, mixed in the lighters moored alongside the caisson. The second half was formed of lime, puzzuolano, and broken stone, in the manner usually practised in the country. The latter was mixed dry at Suez, and was wetted on being deposited.

When the success of the process of depositing the concrete was well assured, the author turned his attention to the Dædalus, which was reached on the 26th of December. A site for the lighthouse was chosen near a small sandbank of triturated coral, as it was determined to use the sand for the concrete, and as it was also convenient for bleaching boats, &c. The surface of this reef was very irregular, there being numerous hollow places, varying from 1 ft. 6 in. to 2 ft. in depth. A four-legged shears was set up on the intended site, and a platform fixed upon it at the level of the under side of the pile collars. Upon this platform was bolted together the plates forming the polygon to complete the inner circle of piles. The six piles were then successfully raised on end, and the collars were bolted to the polygon. When the six piles were fixed, the original stage was removed, and a new one was formed, to receive in a similar manner the outer polygon. This having been fixed in place, and the two polygons connected by the radiators, the outer piles were raised. The caisson plates were then set up, being first bolted together, and then partially rivetted. The whole of these operations occupied seven days and a quarter, the staff employed consisting of four workmen, and parties of from six to eight men from the crew. The lighter "Ushruffee" was then moored upon the reef, and the steamer proceeded to whence it returned with fifty tons of cement and twenty Arab labourers, under a native foreman, for depositing the concrete, and having a second lighter in tow. The concrete here used consisted of three and a-half measures of coral sand to one measure of cement. The first operation was to fill up the holes between the coral lumps with coal bags filled with concrete, so as to make an even surface to lay the tarpaulins upon. The deposit was then carried on in the same manner as at the Ushruffee. The quantity of cement, above alluded to, was only sufficient to comple three-fourths of the required height of the block. This occupied just eight days, and then the author returned to Ushruffee, and finding five tiers of that lighthouse erected and partly rivetted, he handed over the entire charge of both works to Mr. Scott, who shortly after proceeded, with a party of four mechanics, two rivetters, two labourers, and ten Arabs, in all, twenty, besides the crew, to the Dædalus. With these, in twenty-six days, the work being carried on only on twenty-one days, the whole framework was erected and rivetted together, two floors and the water tank were completed, and the lower room was enclosed. Two mechanics and four seamen were then placed in the building, with provisions and water to continue the work, and the "Union," with Mr. Scott and the remainder of the working party, returned to Ushruffee. Thus, in thirty-seven working days, the main portion of the building, now 57 ft. in height, was so far finished as to be habitable for a party sufficient to complete the remaining details. Had the ship been of larger burthen it was believed that these thirty-seven days might have been continuous, and that the whole would have been accomplished during an absence of about seven weeks from Suez. The author referred, in terms of highest praise, to the manner in which what might be termed the nautical part of the undertaking had been carried out by Captain Kirton. Subsequently, the materials for the lantern and lighting apparatus were deposited in the building, and afterwards one leading mechanic, two labourers, and five seamen completed the work between November, 1862, and the 1st of February, 1863, when the light was exhibited.

At the last mention of the Ushruffee the concrete base had been completed, and five out of eleven tiers of framing had been erected. During the absence of Mr. Scott and his party at the Dædalus, a European boat's crew of six men was engaged in conveying the remainder of the materials to the reef, and in sorting them there. On the return of the working party, the erection was rapidly proceeded with, in the face of much difficulty, from almost constant high northerly winds. The time actually taken in erecting the skeleton framework, 106 ft. in height, was two months, and the rivetting was completed within three months. The two succeeding months were occupied with the erection of the lantern and lighting apparatus, and completing the details of the building, and on the 1st July, 1862, the light was first exhibited.

In connection with this undertaking the profession had to regret the loss of a very promising young member, Mr. C. W. Scott, who towards the close of the operations was attacked with symptoms, which developed the seed of a disease of long standing, under which he succumbed after an interval of five months.

With regard to the cost, a mere statement of the total amount expended upon the two lighthouses, £55,211 in all, would convey an erroneous impression, unless accompanied by an explanation. The cost of the whole as an engineering work, independently of the employment of the steamer, might be taken at £32,079, including all contingencies, supposing the reefs to have been within a boating distance, say one mile and a half, and half a mile from Suez. If the steamer had been equipped at Suez, and had been continuously employed, then, on this supposition, the cost might have been £42,082. The remaining expenditure, £13,029, was entirely exceptional, arising mainly from the steamer being equipped at Bombay.

PROGRESS OF THE IRON TRADE IN THE NORTH.

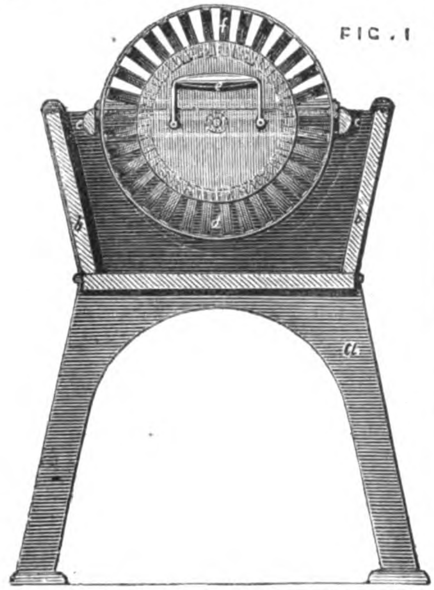
It is stated by the northern papers that Sir W. Armstrong has purchased or leased extensive ironstone beds in the neighbourhood of Bellingham. The old ironworks at Ridsdale-tor are not unlikely soon to be again in active operation, under happier and more successful management than the last. The ironworks at Bishopwearmouth also are about to be re-opened, which will be a great boon to the industrial and trading classes of that part of Sunderland. The iron trade of this district, indeed, extends with almost unparalleled rapidity. Including the Consett furnaces, there are already eighty-one blast furnaces in the Cleveland district, and preparations are making for building fifteen more. The quantity of ironstone sent from the Eston mines for the first six months of the year averaged not less than 13,000 tons per week. In one month the quantity reached as high as 14,000 tons per week! There is every reason to believe that if the trade continues to extend for the next ten years as it has done during the last, that the Teesside will be the largest iron-making district in the United Kingdom.

The Ordnance Select Committee of the War Department has ordered another telegraph cable of the firm of Messrs. Wells and Hall. It is to have four conductors, insulated with caoutchouc of the purest quality, in order to have insulation of the highest degree attainable. The external covering of the cable will be Russian hemp, braided over by a peculiar method, whereby the whole strain in paying out, or hauling in, will not cause any elongation of the cores—as experienced in spiral-covered cables. This cable, moreover, will be free from any twist—consequently, no kinking can possibly occur. The cable is being constructed in accordance with instructions given by Lieut. Noble, R.A., and will be required for submarine use. We believe it is intended for the experiments which are to take place at Shoeburyness with the Armstrong guns. In the experiments, the conductors of the cable will be connected with the floating target (now in course of construction at the Royal Arsenal), the other end will be in connection with the beautiful instrument of "Narvess" for ascertaining the velocity of projectiles. We may here remark, that the most perfect insulation is required in making experiments with this delicate apparatus—hence the cause of having caoutchouc for coating the conductors. We believe all the telegraph wires underground on the practice range at Shoeburyness are insula ted with this gum, and have given much satisfaction, having been two years embedded in the ground.

RICHMOND AND CHANDLER'S IMPROVEMENTS IN WASHING ROOTS.

THIS invention, patented by Messrs. Richmond and Chandler, of Salford, consists in an improved mode of constructing the cylinders or drums in which potatoes or other vegetables are washed; the cylinder or drum is formed with a cast-iron or other frame furnished with trunnions supported in bearings fixed to the ends of the trough containing water as usual; one half of the cylinder or drum is loose, and it is provided with handles by which it is easily removed from the frame in which it fits, and the other half is hinged to the frame, the two halves being connected together and to the frame by a spring catch or otherwise. The circumference and ends of the cylinder or drum (or the circumference only) are made with

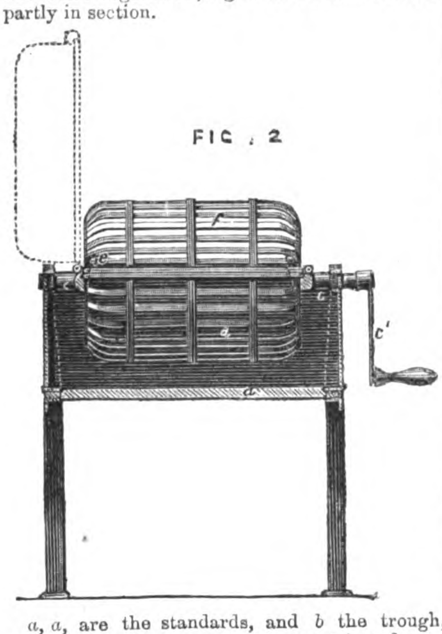
FIG. 1



strips or bars of galvanized iron or other suitable material. By this means the loose part of the cylinder or drum is easily taken out to remove the potatoes or other vegetables when washed, and to replace a fresh supply to be washed, and in some cases the machinery may be supplied with two loose portions to save time in removing the washed and supplying the unwashed vegetables.

Fig. 1 is an elevation in transverse section of the improved machinery for washing potatoes and other vegetables; fig. 2 is a side elevation partly in section.

FIG. 2



a, *a*, are the standards, and *b* the trough, which are made as usual; *c* is a cast-iron frame, the trunnions of which revolve in bearings provided for them in the standards *a*; *d* is the lower half of the cylinder or drum which fits on projections cast in the swing frame *c*; this half of the cylinder or drum has handles *e*, *e*, by which it can easily be lifted out of the swing frame; *f* is the upper half of the cylinder or drum, which is hinged to snugs cast on the swing frame, and when the cylinder or drum is closed, as shown in figs. 1 and 2, the two halves are held together by a split pin, or in any other convenient manner. When the potatoes or other vegetables are in the cylinder or drum, it is turned round in the trough containing the water by the handle c^1; when the vegetables are sufficiently cleansed the lid *f* is opened, as shown in dotted lines in fig. 2; the lower half *d* of the cylinder or drum is then lifted out of the swing frame *c* by the handles *e*, and another one with a fresh supply of vegetables to be washed is put in its place, or, if there is only one loose half to the machine, the same half is put back into the swing frame after the clean vegetables have been removed and a fresh supply has been put in. By this means the operation of washing vegetables can be greatly accelerated and labour economized.

Legal Intelligence.

BEASLEY *v.* BLAKELEY.

On Friday last, a case of some interest was tried at the Court of Exchequer, before Mr. Baron Martin and a common jury.

The action was brought for goods sold and delivered. The defendant pleaded Not guilty.

Mr. Serjeant O'Brien and Mr. Gates were counsel for the plaintiff; and the Hon. G. Denman and Mr. Watson for the defendant.

The plaintiff is the executor of Mr. Astbury, ironfounder, of Smethwick, near Birmingham; and the defendant is the well-known inventor of the Blakeley Gun. In June, 1862, the defendant called at the foundry and ordered a particular gun, on the Sardinian model, to be sent to him, for which he was to pay £75. The gun chosen was rifled to one-twelfth of an inch, but he directed it to be rifled to one-eighth. There being some difficulty in doing it, they substituted another gun, which was similar in every respect to the one chosen, having previously informed the defendant of what he had done, and to which no objection was made. Three weeks after the gun was delivered, a letter was received from the defendant, informing the plaintiff that the gun was not of the description he had ordered, and asking him to take it back; but he declined to do so.

The defence was that a gun was ordered capable of throwing a particular shot, and that the gun sent was not capable of doing so. He therefore sent the gun back. The defendant ordered a gun on the Sardinian model, and the one which was sent was of the American pattern.

The learned judge summed up, leaving it to the jury whether the plaintiff had established the fact that by the non-answering of the plaintiff's letter, and the non-return of the gun, the defendant had entered into a new contract by which he agreed to accept the substituted gun. If there was any wilful misrepresentation as to the make of the original gun, the contract would be void.

The jury returned a verdict for the defendant.

PREVENTION OF DECAY AND OXIDATION IN SHIPS.

(*Concluded from page* 789.)

IN 1852, Mr. J. Murdoch invented a variety of driers for zinc when the white of zinc is employed instead of white lead. The protoxides are manganese, cobalt, iron, tin, and nickel; for acids, the benzoic, urobenzoic, and the boric. In 1852 also, Mr. Binks patented a substitute for linseed or drying oils, in the products derived from dissolving what are called insoluble soaps. A pigment is then ground in this solution, and the paint is ready for application. The pigment may be white lead, oxide of zinc, lamp-black, or any other. J. C. Medeiros, in 1853, proposed the use of mercury or quicksilver on iron plates for sheathing ships. The salts of mercury are dissolved, then a bath is formed, and the plates allowed to remain in the solution till their surface is equally and regularly amalgamated.

Mr. Newton, in 1854, made a paint from ground plumbago, pulverized charcoal, and the black soot formed by the burning of bituminous matter, along with ivory-black, or bone or lamp-black. Mr. Ryder also, in 1854, described a method for mixing gutta percha with common resin, or tar, pitch, or asphaltum, dissolving them in impure benzole or coal naphtha. Mr. Newton took out a second patent, in 1854, for the production of a siccative black, brown, or grey pigment and colouring matter, by the admixture with the gas tar, or other organic substance to be carbonized for the purpose, of the oxides of potassium, sodium, calcium, aluminium, or other alkaline or earthy bases for paints. Mr. F. Ransome, in 1854, patented a mixture, consisting of ground oxides and carbonates of lead or zinc, and carbonate or sulphate of barytes with soluble silica. Mr. J. Rogers, in 1855, to prevent oxidation, deoxidizes metallic ores by a revolving cylinder, fitted with helical or screw-formed divisions to receive the ores in a pulverized state, and then submits the same to heat and constant agitation by the revolution of the cylinder. Mr. B. Rosenburg, in 1855, manufactured a paint as follows:—100 lbs. of triturated white lead, 2½ gallons of copal varnish, 1½ gallon of spirits of turpentine, 1½ gallon of linseed oil, and, for colouring, a small quantity of red lead. Before the metal is painted it is subjected to the fire for cleansing, and when cool the preparation is applied, then varnished with copal, and dried by a hot-air process. Mr. J. E. Cook, in 1855, proposed a composition consisting of gum shellac, dissolved in methylated spirit or in wood spirit. In 1856, the patent of Messrs. Bancroft and White claims the manufacture of oils from petroleum, for preserving metals and ships' sheathing. Mr. A. F. Mennons, in 1856, obtained a patent for a non-conducting and inoxidable composition for metals, made thus:—

Argillaceous clays, containing a certain proportion of alumina	100 parts.
Oily substances and residues	6 ,,
Oil sediment	5 ,,
Fat..	2 ,,
Animal charcoal..........................	2 ,,
Mucilaginous substances, such as glue, &c.	2 ,,
Wood sawdust, already employed in the purification of oils in the processes of dyeing	10 ,,
Waste hair well beaten	4 ,,

To the preceding materials a decoction of logwood and soot is then added.

Mr. J. M'Innes, in 1856, was granted a patent for coating metals with powdered emery stone mixed with a varnish of shellac dissolved in spirits of wine, with the addition of castor oil. As emery contains 87 per cent. of aluminium, Mr. M'Innes considered that this paint would be solid enough to resist all action in the water, and never decompose. Mr. R. D. Atkinson, of Hull, in 1856, invented a plan for coating and protecting metals from oxidation, by depositing copper or brass upon surfaces of prepared iron, the deposit to be melted in conjunction with carbonic acid gas, the coating to be put on by a brush, or through the medium of galvanism. Depositing brass on iron is now being successfully carried out at Portsmouth, by Mr. Wielan on armour plates and other iron surfaces. Mr. A. Reid, mineralogist, in 1856, describes in his specification what he deems a sure way of preventing oxidation. He places the iron in a properly constructed furnace, then covers the metal with soot, or other matters possessing the like element; the temperature is then raised to red or white heat, and continued for half an hour, or according to the size of the iron operated upon. It is then suffered to cool, the surface is cleaned, and Mr. Reid asserts that a coat impervious to rust is formed. If this is verified by positive experiments, the cheapness and simplicity of the plan deserve to be widely known. Mr. Joseph Poleux, of New York, communicates, in the same year, a plan to overcome oxidation. He employs muriatic acid, nitric, or sulphuric acid, of the ordinary degrees of concentration in commerce, without dilution, combined with the introduction of spelter into the cleansing process. In 1857, Mr. G. Bedson patented a new process. He melts a quantity of pitch derived from mineral tar, and a proportion of tar oil, with caoutchouc tempered with tar oil and shellac, the substance to be solid and elastic when cold. Mr. C. F. L. Oudry claims depositing copper on a preservative or intermediate coating instead of on the metal. He deposits copper in a pure state to any thickness on all metals. Mr. C. Iles, in 1857, de-

scribed a means of applying earthy cements to metals. In 1858, Mr. J. Coutts received a patent for applying the following pigment by heated air :—

Carbonate of baryta	·650
Litharge	·065
Arsenious acid...	·030
Asphaltum	·050
Oxide of Calcium	·030
Creosote (oil of tar)	·175

Perhaps the most novel introduction is that patented here by Messrs. Bouchard and Clavel, the Paris bankers, in 1858. On the estate of La Gruerie, in Charney, Department of Yonne, France, is found an earth of the ochre description, called "Burgundy Red." This earth contains most valuable properties, and is said to be an exceedingly good preservative against rust. It is used as a cement and paint by admixture with the following :—

Burgundy red	66 parts
Grease or oil	15 ,,
Lime	11 ,,
Unburnt earthenware, chalk, or Roman cement...	8 ,,
	100 ,,

This is said to prevent oxidation if the earth is merely diluted with volatile oil. D. M'Crae, in 1858, was allowed a patent for preserving bottoms of ships from fouling or decay. He applies grease from the cells of boiled bones, kitchen stuff, and butter without salt; a poisonous matter is mixed with these fatty substances. Mr. G. P. Lock, in 1858, made a composition for the under-coating of iron ships, made from iron ore ground in boiled linseed oil 50 per cent., oil of turpentine 50 per cent., well mixed. For the outer coatings, white lead 40 per cent., blue mineral or copperas 10 per cent., and oil of turpentine 50 per cent. In 1859, Mr. Henry, on the part of Moisant and Co., sought protection for bituminous products and compounds of bitumen for preventing oxidation. Mr. T. J. Laballe, made a preparation of caoutchouc paints and colours for vulcanising. Mr. J. Crawford, of Liverpool, in 1859, applied for a patent for a metallic paint or varnish, composed of plumbago, or black-lead, fine or gum varnish, arsenic, and spirits of turpentine mixed. Mr. F. W. Emerson, in 1859, prepared an anti-corrosive paint from oxi-chloride of lead, mixed and ground with oil, turpentine, varnish, or other vehicle. Mr. Weild, in 1859, sought to economise time and labour by a mechanical machine for applying paints to metals on large surfaces. Mr. James Meikle, in 1859, proposed coating iron ships with asphalte. In the same year, M. Auguste Pin dissolved sugar in muriate of zinc, then added wax and soap, in which was incorporated calcareous stones, phosphate of soda, sulphate of zinc, and copper, and the syrup of potatoes or sugar, with powdered marble, quartz, or felspar.

In 1859, Mr. F. G. Spilsbury, of Louvain, applied for a patent for the manufacture of a paint. He took sulphate of lead, and heated it to a red heat, either by itself or mixed with alumina or other earths; the pigment thus obtained to be washed first with sulphuric acid, then with water, when it is finally dried. Previous to drying the pigments they are digested with salts of tungstic acid, molybdic acid, titanic acid, tantalic acid, arsenic acid, acid of antimony, or other metallic acid, or with mixture of the above salts. A combination between the sulphate of lead and the metallic acid or acids is obtained, and the resulting pigments are dried in like manner after having been cleared from all adhering salts. The pigments may then be mixed with oil and used as a substitute for white lead. Mr. J. F. J. Lecocq, in 1860, prepared a calcareous varnish for coating iron and the bottom of ships. Mr. H. Kemp, in 1860, patented a composition consisting of peat, tar, wood tar, methylated spirit, peat oil, or linseed oil, arsenic resin, and carburet of iron, for preserving ships' bottoms. Mr. Allen's plan of making a coating or anti-corrosive paint for metals is thus given :—Ammoniacal liquid obtained from coal tar, or gas tar, prevents incrustation in boilers, and is applicable to painting the inside plates. Messrs. Pile and Symth, of West Hartlepool, took out a patent in 1860. They employ a red composition and enamel, consisting of a combination of litharge, Venetian red, and pine varnish. Over this composition is applied a coating of resin, gums, or any pitch or bituminous substance, with the addition of coal tar, or oil. This is put on in a hot lava state, and the process is called enamelling. An impermeable oil varnish was patented by M. Antoine Bonet in 1860, composed of 100 parts of alcohol, 100 parts of spirits of turpentine, one part of sulphuric ether, and one of carbonate of soda.

Mr. Robert Smith, shipowner, of Finsbury, applied to the Patent-office, in 1860, to protect his system for keeping vessels from fouling and worming. He applies equal parts of pitch, tar, resin, and turpentine, with any other adhesive compound. Assafœtida to be mixed with the foregoing, as a poison to destroy life. When the coating is laid on, and dry, the whole to be covered with paper or cloth. Mr. G. Hallett, in 1860, in his patent explains his method of protecting metal. He grinds the oxide of antimony to powder, then dries it, and mixes with it 12 lbs. of linseed oil to the hundredweight of powdered oxide. Mr. Richardson, in 1861, to prevent oxidation, would cover the metal with vulcanised india rubber, cloth, or gutta percha, the object sought being to provide for unequal expansion of the metal and coating. Mr. Francis Pulz, chemist, in 1861, causes oxygen to be passed through sulphuric acid, to render the oxygen more active as an oxidizing agent, as it combines, when so treated, with other substances for which it has an affinity, for manufacturing purposes. Mr. Pulz, also, in a second patent, submits oily matters to this oxidising agency, by causing the sulphuretted gas to pass through them when in a liquid state. Mr. Martin Miller sends a communication, in 1861, for coating metals by metals or alloys in different ways. Mr. John Hay, in 1861, patented a drying oil. He lays a non-conducting coat, and then makes a paint by grinding in linseed oil the black or protoxide of copper, which is then boiled till reduced to the sub-oxide, and by thus oxygenating the oil he claims to have formed a quick drying cupreous oil. Mr. John Snider, of the United States, patented here a compound, in 1861, for coating metal. He reduces amorphous graphite to fine powder, and then mixes it with ore by the agency of a heated steam pipe. When cool and dry, one pound of oil is added to three pounds of the powder, and when the ingredients are combined, hot pure beeswax, in the proportion of one pound of wax to 10 lbs. of graphite, is mixed. Afterwards linseed oil may be added. Mr. Snider details his manner of manipulating and preparing the graphite and ore. Messrs. Hallett and Stenhouse, in 1861, obtained a patent for the manufacture of pigments for coating surfaces. They employ native oxide of antimony, chemically treated in ways too intricate for explanation in this abbreviated outline, and mixed with red lead or litharge. They sometimes take type metal or worn-out types, reduce them to a coarse powder, and then mix them with their own weight of zinc, and calcine them. This produces a yellow pigment.

CORNISH PUMPING ENGINES.

At the meeting of the Institution of Civil Engineers, held on Tuesday last—J. R. McClean, Esq., Vice-President, in the chair—Mr. W. Morshead, jun., read a Paper on the "Duty of the Cornish Pumping Engines."

It appeared from a tabular statement prepared by the proprietor of "Lean's Engine Reporter," for the years 1841 to 1860 inclusive, that the average duty of these engines had fallen off from 68 millions in 1844 to 52 millions, in 1860, or 25 per cent.; also that less interest was now felt in the performance of these engines, as while fifty were reported in 1841, only fifteen were reported in 1858, and twenty-five in 1860. Although the nominal, or reported duty, showed this marked diminution, it was not asserted that there had been an actual falling off to the extent thus indicated—for the duty paper did not take into account the quality of the coal, which was certainly inferior to that used twenty years ago; besides which the present practice of sinking the engine shaft, for the whole, or part of its depth, in an inclined direction upon the course of the lode, must have tended to increase the friction of the pitwork, and the mines were also deeper than formerly. Nor was expansion of steam adopted to so great an extent now as it was some years ago; it was then carried further than was compatible with safety, as was evidenced by the repeated breakages of the main rod, the piston rod, and the other principal parts of the engine. But after allowing for all these legitimate causes of the falling off of duty, it was thought that the average duty of the county was still at least ten millions below what it should be.

The author next examined the causes of this decline, and then discussed the means by which it might be remedied. The primary cause he believed to be, the indifference of the mine proprietors to the performances of the engines. So many accidents attended the use of high steam, cut off at an early part of the stroke, that economy of fuel came to be regarded as synonymous with repeated breakages; but it was quite possible to raise the duty considerably above the present average, without resorting to an undue rate of expansion. This might be accomplished by a more perfect and extended system of reporting the engines, and by a new form of duty paper, embracing the following additional items :—First, that the load upon the piston should be taken from an indicator diagram, and from the load thus ascertained the duty should be computed, the difference between the load upon the piston and the weight of water actually lifted—that was, the loss by the friction of the pitwork, &c.—being placed in a separate column. Secondly, that the part of the stroke at which the steam was cut off as well as the vacuum obtained, should be stated opposite each engine. Thirdly, that a notice of the quality of the coal used, as far as it could be ascertained, should be added. And lastly, that the engines should be separated into two classes—those which might reasonably be expected to give a good duty, and those which, from the time they had been at work, their small size, or other causes, could not fairly compete with the former. By taking the load upon the piston from an indicator diagram, a fair estimate of the work actually done by the engine could be formed, while by placing the difference between the load upon the piston and the weight of water actually lifted in a separate column, encouragement was offered for improvement in the construction and fixing of the pitwork.

At present, only about one-tenth of the engine at work in Devon and Cornwall appeared in the monthly reports. If mine proprietors would co-operate in supporting a good form of duty paper, there was little doubt, but that there would be a rapid and marked improvement in the duty of the Cornish engines.

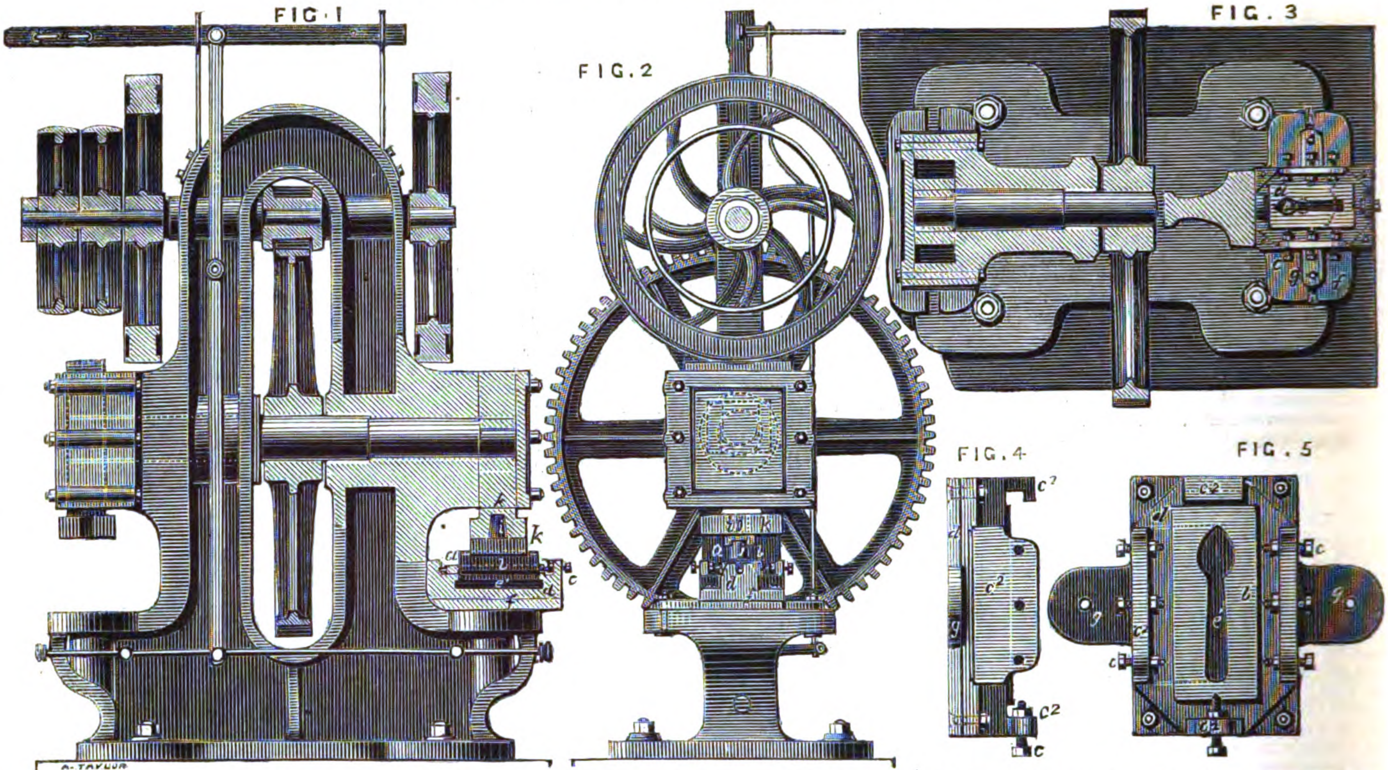
NADAR'S GREAT BALLOON.

The "Géant," now at the Crystal Palace, is by far the largest balloon ever yet made. Its entire height, including the "compensator"—a small balloon under the large one, containing a reserve of condensed gas—and the car, is close upon 200 feet, and when fully inflated it will contain 215,363 cubic feet of gas. For greater security it has two skins, both of white silk—the outer coloured a yellowish white—of the finest quality, and of which more than 20,000 yards were consumed in the manufacture. All the gores are entirely hand-sewn, and the work occupied 300 men and women for more than a month. Perhaps we shall give the best idea of its magnitude to English readers, by saying that it could not be got into one of Captain Fowke's great domes. It is easy to understand, too, how hard it must be to control this enormous body of gas so as to manage a safe descent; and novices in aëronautics may be permitted to doubt whether, until the valve machinery is improved, safe voyages can be performed by balloons of such a size. M. Nadar himself, attributes the unfortunate issue of his last trip more to the deficiencies of the valves, which did not permit the gas to escape with sufficient rapidity, than to the failure of the anchors. The "Géant" is calculated to lift $4\frac{1}{2}$ tons.

The car is a great curiosity in its way. In its outside appearance it is not unlike, on a small scale, one of the caravans to be met with by the side of a gipsy encampment. It is about 15 ft. long, by 12 wide, and is partitioned off into a captain's cabin with sleeping berth, four small cabins with berth, washing room, and printing and photographic operating rooms. It is fitted with wheels on moveable axles, so that there may be no difficulty in the return, supposing a descent to be effected far from the ordinary means of transport. There are windows and doors on each side; but, after all, there does not seem much room for nine people to turn in comfortably. For those who prefer the open air there is the roof, with which a strong high bulwark running round makes a kind of airy terrace or quarter-deck.

We are informed that a substitute for cotton has been discovered by a firm in Liverpool, with which length of fibre, delicacy, elasticity, and great strength, are equal, at least, to Indian cotton. It can be produced to any amount at 6d. per lb. It has been patented in France; and its applicability and utility are so evident, that the Minister of the Interior has intimated his intention of forwarding its use by all means in his power.

BROOMAN'S IMPROVEMENTS IN THE MANUFACTURE OF SPOONS AND FORKS.



BROOMAN'S IMPROVEMENTS IN THE MANUFACTURE OF SPOONS AND FORKS.

THIS invention, patented by Mr. R. A. Brooman, of Fleet-street, relates to the manufacture of spoons and forks from sheet metal, as hereafter described. The patentee uses an ordinary cutting-out or stamping press, on the bed of which are placed matrices, corresponding stamps or dies being fitted in the head. These matrices and stamps are changed according to the progress of the work or the particular part of the work to be performed.

The patentee first takes a frame and adjusts therein a matrix, in one or more pieces, of the contour of the spoon or fork to be made. This is placed on a counter-matrix, in which there is an inclined channel for receiving and leading away the piece of metal stamped from the sheet, as hereafter explained, and the frame is fixed on the bed of the press. A stamp or punch corresponding with the matrix is fixed in the head of the press. Sheet metal being placed on the matrix and the stamp or punch brought down, a blank, having the outline of a spoon or fork, is cut or stamped out, which falling through the inclined channel is removed for the second operation; which consists in turning up, in a matrix and stamp for the purpose, side-pieces between the part for forming the bowl or prongs and the handle. The third operation consists in turning down and consolidating the side-pieces so raised by another matrix and stamp; while the fourth operation consists in hollowing out the part intended for the bowl or for the prongs by means of a matrix and stamp constructed and shaped for such purpose. The fifth and last operation, for giving the finished shape to the article, is performed in a matrix and stamp prepared for that purpose.

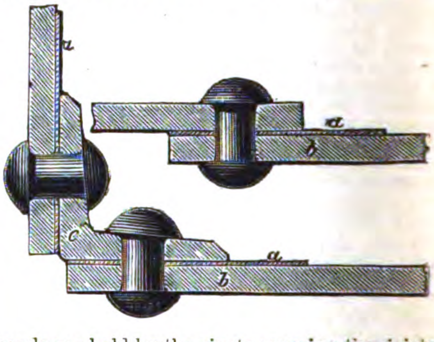
Fig. 1 of the accompanying drawings is a longtitudinal section, fig. 2 an end view, and fig. 3 a plan, of an ordinary cutting-out or stamping press suitable for carrying this invention into effect. a is a matrix, which is placed on a counter-matrix b, and fixed by screws c, c, passing through lugs c_2 of a frame d. The matrix a may be in one piece or in two pieces. The counter-matrix b is formed with an opening e^1 corresponding with the opening e of the matrix a; the opening e^1 is continued downwards in the form of an inclined channel for receiving and leading away the piece of metal stamped from the sheet. The frame carrying the matrix and counter-matrix is fixed on the bed f of the press (figs. 1, 2, and 3) by means of screws or bolts passing through lugs g, g, fig. 5, into slots h of the bed. i is a stamp or punch carrier fitted in the head k of the press, and receives in its dovetail a stamp or punch of a shape corresponding to the spoon or fork blank to be cut or stamped out. When a spoon or fork blank is cut or stamped out, it falls through the inclined channel e^1 into a receptacle placed to receive it. The next operation is to shape the spoon or fork to the form required by turning up side-pieces o, o. This is performed by substituting a second matrix for the one on the bed of the press, and a different punch for the stamp or punch represented, and by bringing down the stamp or punch as before. The third operation consists in turning down and consolidating the side-pieces by another matrix or punch. The three operations above described may be performed in the press (figs. 1, 2, and 3) by simply changing the matrices and stamps. The fourth and concluding operations are performed in the same way by changing the punches and matrices, or by the aid of a separate fly-press.

WILDE'S IMPROVEMENTS IN THE CONSTRUCTION OF STEAM BOILERS.

THE nature of this invention, by Henry Wilde, engineer, Manchester, consists in a method of constructing steam boilers by which the peculiar kind of corrosion, known as furrowing, is greatly diminished or entirely prevented.

It is well known that this furrowing occurs in the immediate vicinity of a seam of rivets, and near the edges of the angle iron which joins the ends to the shell of the boiler, and also in other parts where one piece of iron in a state of vibration and tension is in contact with another piece, either in its normal condition or in an unequal state of vibration and tension.

In constructing boilers according to these improvements a fillet or band of thin sheet copper or other suitable metal, marked a, having holes punched through it corresponding with those in the boiler plates b, b, is placed between the plates b and the angle iron c, and between the end plate d and angle iron c, and also between the plates where they overlap each other to form the transverse and longitudinal seams. The fillets or



bands are held by the rivets securing the joints, and they are of sufficient width to extend beyond the joints in the interior of the boiler, and to overlap or cover those parts of the plates where the furrows are usually formed.

Instead of placing a fillet of copper or other suitable metal between the plates, as above described, the boiler plates may be coated with copper or its alloys by any of the well-known methods for the purpose of producing the same result.

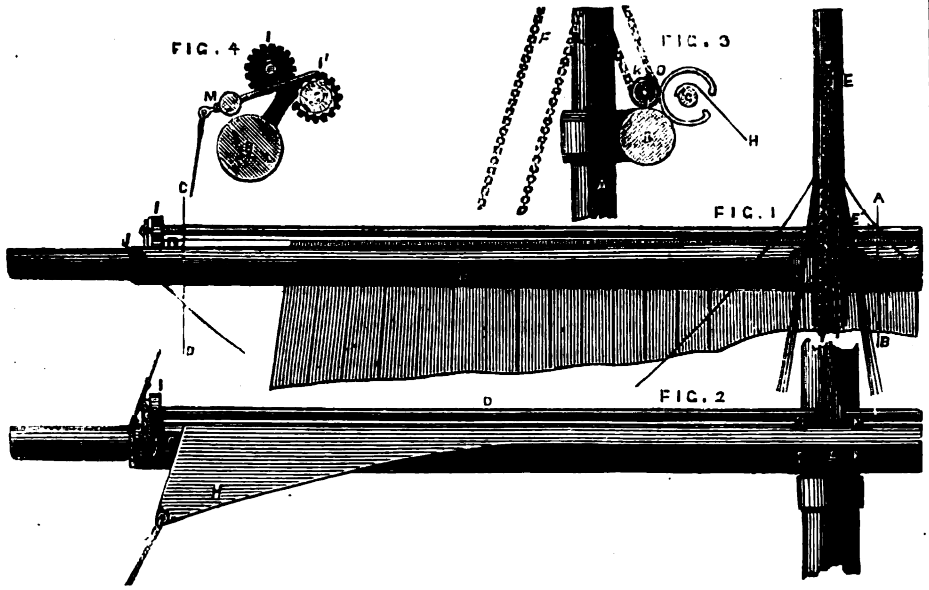
The above improvements are also applicable to boilers made of steel plates.

WILLETT'S IMPROVEMENTS IN REEFING SAILS.

THIS invention, patented by Captain Willett, London, has for its object a very simple but most efficient arrangement for furling or reefing top or square sails from the decks. It can be adapted to the square sails of any ships, and does not require the sail to be in any way altered or divided, as is required in many of the existing reefing apparatus.

Its simplicity of construction renders it much cheaper, and at the same time less liable to get out of order.

WILLETT'S IMPROVEMENTS IN REEFING SAILS.



The sail is bent to a wooden roller secured on the fore part of the yard by suitable bearings at each end, and supported in the centre by a roller claw firmly secured to the mast, and of sufficient size to receive the entire sail when wound up on the roller spar. A solid or hollow metal rod of equal length to the roller spar is secured, and turns in suitable bearings fixed near the ends of the yard, and forming part of or closely connected with those in which the roller spar turns. Each end of the metal roller is furnished with a cog wheel, which gears with a similar wheel on the ends of the roller spar. On the centre of the metal roller is a chain wheel, grooved similar to the chain wheel of a clock, for the purpose of forming a secure hold for a chain, which, after passing over it, is led through two sheaves fixed in the mast, one a short distance above the other, but both higher up in the mast than the yard would be if the sail was set. The chain is of sufficient length to permit the furling and unfurling of the sail; and the two ends are attached to two haliards, by which the apparatus is worked from the deck. Thus when the sail is set, by slackening away the upper haliards, the yard will descend from its own weight, and the metal rod will be put in motion by the slackening of the chain, and communicate its rotary movement to the roller spar by means of the cog wheels, and so reef the sail to any size required. By tightening the upper haliards the sail is set. The above description will be readily understood by aid of the accompanying drawings.

Fig. 1 is a back view of the sail; fig. 2 is a front view, showing the yard supporting the roller spar, with the sail nearly furled; fig. 3 is a sectional side view, showing the chain wheel over which the chain passes, and the roller claw; fig. 4 is an enlarged sectional view (following the line C, D,) of the cog wheels on the metal rod and the roller spar, and also the bearings which support the ends of the metal rod and roller spar.

A represents the mast; B, the yard supporting the roller spar C, to which the sail H is bent; D is the metal rod, in the centre of which is fixed the chain wheel K; E and E^1 represent the upper and lower sheaves over which the chain F passes; F, the chain, which after passing over the lower sheave E^1, is passed round the chain wheel K, and then over the upper sheave E; the chain F, on leaving the chain wheel, is made to pass up the side of the mast, slightly hollowed out for the purpose; G, the haliards attached to the ends of the chain F, and descending to the decks; H, the sail; I and I^1, cog wheels on the metal rod D, gearing with the cog wheels J and J^1 on the roller spar; K, chain wheel on the metal rod D, and put in motion by means of the chain F, worked by the haliards from the deck; L, claw furnished with friction rollers, and serving as support to the roller spar on which the sail is bent; M, self-acting paul for the purpose of holding the roller in case of accident. Both the cog wheels and the paul, should one be made use of, may be boxed over as a protection, and to prevent ropes from entangling in them.

MAKING HORSE-SHOES BY MACHINERY.

Although this branch of trade makes small progress in England, it appears to be carried on with some success in the American States. Horse-shoes are now manufactured in large quantities at Providence, R.I., and at Troy, N.Y., the machines, however, being entirely different in construction at the two places. At Providence the shoes are all made from scrap iron, fagoted up, welded together, and afterwards rolled into long rods. These rods are creased for the nail-hole in passing through the rolls, and afterwards punched complete in one operation—eight holes being made in each one. The shoes are bent into shape by a peculiar apparatus, and hammered by a trip-hammer while in the machine, so that they do not spring when taken out or alter in shape. It was a matter of great doubt among mechanics at one time whether horse-shoes could be made by machinery to equal those produced by hand-labour; but, we believe, all apprehension on this score is set at rest, and that machine-made shoes are in all respects as good as those made in the old-fashioned way. The Providence factory is now running night and day, turning out 200 tons per month for Government use.

NEW MODE OF FIRING MINES BY ELECTRICITY.

This new fuse, invented by MM. Comte and Gaiffe, which will, it is hoped, render incalculable service in the working of mines and the excavation of tunnels, differs from those which have been employed hitherto, in a novel arrangement of the parts of which it consists, which permits of its manufacture in a very short space of time, and reduces the chances of fracture to a minimum. It consists, first, of an insulated wire, to which is affixed the usual fuse tube; secondly, of another wire, uninsulated, twisted round the first, with its extremity removed one centimetre from that of the insulated wire; and lastly, of a bag containing the explosive compound, within which are buried the extremities of both wires. When the induced current from a Rumkorff coil is passed through the wires, the spark, on account of the distance which separates them, passes through the powder contained in the bag. The thread of tin which is employed to complete the circuit in the first instance, is melted instantaneously, and a considerable space then exists between the insulated and the uninsulated wires, through which the spark passes. By this arrangement, it is possible to affix upon two wires proceeding from the coil as many fuses as may be thought fit. The current having passed through the first proceeds to the second; from that to the third, and so on; and because the sparks from Rumkorff's coil succeed one another with great velocity, a great number of mines can be exploded almost instantaneously. So far, the invention has been pronounced by the French press perfectly successful, the experiments which have been made leaving nothing to be desired.

RAILWAY BRIDGE ACROSS THE TIBER.

The *Journal of Rome*, for one of the last days in October, contains the following:—"Yesterday the Pope visited the works now being carried out on the new iron swivel bridge across the Tiber, which is intended to carry the railway from Civita Vecchia to the Central Station within the walls of Rome. His Holiness proceeded to the bridge on foot, and attentively examined all the details. He willingly assisted at the manœuvre of opening one-half the colossal structure, to permit the passage of some sailing ships and steamers. The operation was executed with remarkable care and expedition. Two steamboats, proceeding in contrary directions, passed through without difficulty at the same time. His Holiness made some complimentary remarks to the engineers, and returned to the Vatican." The bridge in question is the first of the new "suspended" bridges invented by M. Alphonse Oudry; in which the cables are so disposed that oscillation is completely obviated. It is said that an eminent engineer has conceived the gigantic project of throwing one of these structures across the straits between Reggio and Messina, and, subsequently, should this scheme succeed so far, to put England and France in direct communication by similar means.

RUSSIAN PREPARATIONS FOR WAR.

From whatever source the Emperor's apprehensions arise, he appears determined to prepare for the worst. Cronstadt is being strengthened under the superintendence of General Todtleben and General Zareva, by placing the old forts in a better state of defence, and at many points covering up the masonry by earthworks. On the main island of Cronstadt, seaward, large earthworks are being thrown up, some of which are nearly finished. Some of these earthworks, more exposed than others, are to be covered with 7½-inch plates, placed on an angle of 45 deg., and curved over the top, so as to form a cover from vertical fire, and at the same time obviate the necessity of having bolts or any other fastenings to retain the plates in position. The embrasures will be closed immediately the gun is fired by a slide of 11-inch iron, or by a drop door. The guns to be placed in those iron-clad and other earthworks, are to be 9-inch rifled cast steel, carrying a 300lb. rifled shot, or a 250lb. shell, 22 inches long.

Another means of defence is also in course of preparation—a submarine boat of colossal dimensions, in the construction of which about 200 tons of iron and steel are to be used. It is rapidly progressing towards completion. Great secrecy is being used about this boat. Nevertheless, the *Times* states authoritatively that it is to have engines worked by compressed air, to have a very strong beak, with provision for attaching large cylinders charged with powder to the bottoms of vessels, to be fired by electricity. The parties navigating the vessel will see what they are doing by means of bulls'-eyes, and they will be able to regulate the depth at which they swim, generally keeping quite close to the surface. The Emperor has not only approved the plans, but some months since signed the decree appropriating about £27,000 for this monster.

The utmost activity prevails in the Ordnance Department; Krupp has his hands nearly full in preparing a supply of steel guns of the largest size. The authorities are erecting a mill at Colpino, near St. Petersburg, and propose to have a second mill built at once, that they may be able to produce 10,000 to 12,00 tons of armour-plates per year. Stirring times these for the Continental engineers!

The armour-plated frigate "Sebastopol" has just been launched at Cronstadt with success. She is to carry engines of 1,000-horse power, and will be armed with 38 rifled guns. The "Sebastopol" is covered with iron plates throughout. On the slip from which she has just been launched another vessel of the same rank, to be called the "Emperor Nicholas," is soon to be laid down, and will, it is expected, be ready for launching in the spring.

TO CORRESPONDENTS.

The Mechanics' Magazine is sent post-free to subscribers of £1 1s. 8d. yearly, or 10s. 10d. half-yearly, payable in advance. Post-office orders made payable to Mr R. A. Brooman, of 166, Fleet-street, E.C.

Advertisements are inserted in the Mechanics' Magazine at the rate of 6d. per line, or 5½d. per line for 6 insertions, 5d. per line for 13 insertions, 4½d. for 26 insertions, and 4d. a line for 52 insertions. Each line consists of about 10 words. Woodcuts are charged at the same rate as type. Special arrangements made for large advertisements.

All communications should be addressed to the Editor, 166, Fleet-street.

To insure insertion in the following number, advertisements should reach the office not later than 5 o'clock on Thursday evening.

Received.—W. and H.—W. B.—H. E.—G. C.—J. N.—W. B.—W. W.—J. H.

S. B. (Belfast).—Use 11-16th rivets spaced 2 in. apart from centre to centre.

Buer (Minories).—Use a pound of good copper and one ounce of tin. If this is too expensive, try 20 oz. of copper, 10 oz. of zinc, 2 oz. of tin, and a little lead. This mixture should be melted twice before using it. It is suitable enough for coarse shafting at a slow speed under moderate pressure. It may be greatly improved by a mixture of old brass.

A Mining Engineer.—We must refer you to our advertising pages.

T. Y.—The only principle involved in the construction of hydro-carbon lamps, is the supply of the necessary quantity of oxygen to the flame by means of a deflector, the construction of which varies according to the ideas of different inventors.

Azote (Walthamstow).—We really cannot state what opinions on the subject of aërial navigation are held by the French engineering world. The Continental papers argue the question *pro* and *con*, at great length, with much acerbity.

Correspondence.

STRESS UPON BOILERS AND BOILER PLATES.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

Sir,—The strength and uniform thickness of boiler plates are usually determined upon the assumption that, from the pressure of the steam upon the surfaces, there are two strains acting upon the metal forming the cylinder—one in the direction of the length of the boiler, from the pressure of the steam upon the circular ends; the other from the pressure of the steam upon the concave surface of the cylinder, in the direction of the radius, tending to split the boiler into two equal parts in opposite lines, at the extremities of a diameter in the cylinder parallel to the axis of the boiler, which latter strain is manifest, supposing the boiler metal to be perfectly rigid and inelastic.

But since metal plates are not perfectly rigid and inelastic—being, though the elasticity be but small, imperfectly elastic—it may, perhaps, be of some use to consider whether a third force, acting in the direction of the radius as before, ought not to be taken into account in determining the form and the thickness of the plates, which force, as it so appears, has a *tendency to change the cylindrical form of the boiler;* the greatest diameter, strain, tension, and compression of the metal being at the middle of the length of the boiler. The amount and effect of the stress referred to will more plainly appear by the following example:—

Suppose a boiler to be 240 in. long, 42 in. diameter, 132 in. circumference, pressure of the steam 40 lbs. per square inch, then the pressures and strains upon the surfaces and the metal plates will be as follows:—

Stress upon the boiler in the direction of the length of the boiler, from the pressure upon the circular ends,

$42 \times 42 \times \cdot7854 \times 40 = 55,417\cdot8$ lbs. ....(1)

Stress upon the internal surface of the cylinder in the direction of the radius perpendicular to the surface of the boiler,

$240 \times 132 \times 40 = 1,267,200$ lbs.........................(2)

Stress to split the boiler into two equal parts in opposite lines in the circumference of the cylinder, parallel to the axis of the boiler, from the last-named pressure (2),

$240 \times 42 \times 40 = 403,200$ lbs............................(3)

The strains (1), (2), and (3) are nearly as the numbers 44, 1,000, and 318 respectively, strains (1) and (3)—or, being the greatest, strain (1) only—being those by which the thicknesses of boiler plates are usually determined.

Suppose the circumference of the cylinder to be divided into 132 equal parts, forming, say, a polygon of 132 equal sides, each side being 1 in., or nearly so, in width; and suppose, also, one of these sides to be detached and fixed in a horizontal position, we should then have a strip or bar of metal 240 in. long clear of the supports, 1 in. in width by the thickness of the plate; then, taking the strains as they are in the boiler, the stress upon the metal bar, in *three* directions, will be as follows:—

Strain in the direction of the length,

$\frac{55,417\cdot8}{132} = 419\cdot83$ lbs. ....(4)

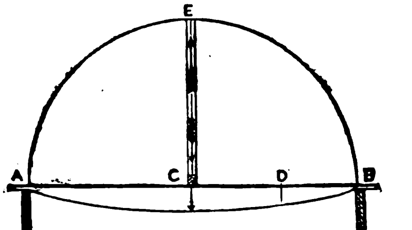
Transverse strain upon every inch in length, at right angles to the last strain,

$\frac{403,200}{2 \times 240} = 840$ lbs...(5)

Vertical pressure, 40 lbs. upon every inch in length, $240 \times 40 = 9,600$ lbs. ....(6)

The strains (4), (5), and (6) are as the numbers 1, 2, and 22·86 respectively.

Let A B represent the metal bar, 240 in. long; bisect A B in C, then the stress at C, from the vertical pressure 40 lbs. upon every inch in length will be 4,800 lbs., and the stress upon the bar and upon the boiler at 1, 2, 3, 4, 5, 6, 7, 8, 9, and 10 ft. from the ends A and B, will be as the numbers 19, 36, 51, 64, 75, 84, 91, 96, 99, and 100 respectively. The stress at C, 10 ft. from the ends, being 4,800 lbs., the stress at 1 ft. from the ends will be $\frac{19}{100} \times 4,800 = 912$ lbs.; at 2 ft., $\cdot36 \times 4,800 = 1,728$ lbs.; at 3 ft., $\cdot51 \times 4,800 = 2,448$ lbs., about one-fourth of the uniform pressure; and so on, at other distances. If the thickness of the metal Dc, at any point D, in A B, varied as the square root of the rectangle $A D \times D B$, or at 1, 2, 3, 4,......10 ft. from the ends as the square roots of the numbers 19, 36, 51, 64,......100, or as 4·36, 6, 7·14, 8,...and 10 respectively, then the strength of the metal plate A B, to resist the uniform pressure, 9,600 lbs., would be everywhere proportioned to the stress; and the boiler, from that one force alone, would no sooner burst in one place than in another. If the metal, instead of being curved, were of a uniform thickness, the mechanical rule, "the strength as the stress," might be approximated by circular bands or hoops surrounding the plates, increasing in strength, at intervals, from O, at the ends A and B, to 1, at the middle of the boiler at C. At the middle point C of the metal bar, instead of one force only, we have three forces, acting at right angles one to another, as before stated, namely—



Stress at C, in the direction of the length A B	419·83 lbs. (7.)
Stress at C, upon one inch in length, at right angles to A B	840 lbs. (8).
Vertical Stress at C	4,800 lbs. (9.)

The strains (7), (8), and (9) are as the numbers 1, 2, and 11·43 respectively. Query—Are there any published experiments upon metal subjected to two strains, and to three strains; and if so, what are the results, supposing the strains to act upon the metal simultaneously and separately?

Suppose the boiler to be cut by an horizontal plane through the axis dividing the same into two equal parts, the plane or plate resting upon the two parellel edges of the lower one-half of the boiler, as in the figure: A B = 3 ft. 6 in., representing, in this case, the width of the boiler.

Let a metal bar, 240 in. long, 1 in. in width, weighing 40 lbs every inch in length, be placed at C, the middle of the plate, parallel with the edges of the cylinder, then the stress upon the edges of the cylinder, at A and B, from the weight at C, will be the same as from the pressure of the steam at E; and the effect, from the weight of the bar at C, on the beam or plate, 20 ft. wide, 3 ft. 6 in. long, will be similar to the effect from the pressure of the steam upon the boiler at E, the effect from the former being to deflect and break the beam or plate A B at C, and the effect from the latter being to expand and burst the boiler at E, and, in like manner, at the remaining 131 sides of the polygon. The effect from the latter pressure might be shown in a model, by connecting two circular wood plates by an axle, covering the same with some flexible material, secured to the circular plates, and subjecting the same to atmospheric or other internal, pressure.

In connection with this subject, and in conclusion it may be remarked that in mixing metals if the tension *plus* the compression of the metal, within the elastic limits, be a given quantity, that metal will be the strongest possible in which the strength in tension is equal to the strength in compression, the neutral axis being in that case at the middle of the depth—this would be the best position of the neutral axis, if the metal, as in the weight upon a beam, were subject to one stress only; but if the metal, as in a boiler, be subject to two strains (both in tension) or to three strains (two in tension, one in tension and compression), the position of the neutral axis, for the metal to be of the greatest strength, would vary according to the strains upon the metal beam or plate.

I am, Sir, your obedient servant,

William Lea, Surveyor.

3, Highgate-place, Birmingham, Nov. 16, 1863.

VENTILATING SHIPS.

Sir,—Perceiving that you are giving a summary of the means which have been, from time to time, proposed for the prevention of decay or dry-rot in timber-ships, I beg to call your attention to a plan which I have lately introduced in connection with ventilation, and which, I think, will be found very effectual, besides serving another very important purpose, that of preventing or removing all foul smells from ships, and effecting a thorough ventilation of all the ships' timbers, as well as of the inhabited deck. The leading feature of my (patent) system is the conversion of *all* the timber spaces or openings into branch air channels of an air shaft on each side of the ship, having apertures of communication of regulated size between it and them. This longitudinal air-shaft, on each side, is communicated into the funnel in steamers by a cross-shaft, or into tube and cowl ventilators in sailing vessels used as uptakes. Thus it will be seen that by this means a circulation of air takes place through the whole framework of the ship, drawn from the passenger deck through the openings above the shelf piece, and from the bilges through all the lower outlets of the timber spaces; the foul air from the bilges and hold—if with such a constant circulation it can continue foul—is vented clear of the ship, instead of polluting the air of the mess deck as at present. This plan has been carried out under my superintendence, by order of the Lords Commissioners of the Admiralty, in the "Royal Sovereign"—steam cupola ship—and a very slight increase of temperature in the funnel draws a current of air through this extensive system of air-shafts and natural channels sufficient nearly to extinguish a candle in the two main shafts, each of which is 18in. by 8in.; of course, when the fires are lighted it would be infinitely increased. When it is considered what extensive timber surfaces are contained in these "timber spaces" thus made by a simple contrivance branch and channels of an active ventilating system, the importance of the circulation thus established becomes manifest; the passive circulation hitherto taking place through them was notoriously inadequate to prevent dry-rot or dampness, which, with insufficient ventilation, to the cause of dry-rot.

I am, Sir, your obedient servant,

Henry Edmonds, M.D.,

Staff Surgeon, Royal Navy.

Portsmouth, Nov. 16.

STEAM FIRE-ENGINES.

Sir,—We will thank you to allow us to correct an error in Mr. Roberts' Paper on Steam Fire-Engines, which was published in your journal a week or two since.

The pumps of our "Sutherland," first-prize steam fire-engine, were *not* "primed" or charged at any time during the Crystal Palace trials, nor have they ever been primed.

The Committee remark thus of this engine in their report, "*pumps not primed.*"

We are, Sir, yours respectfully,

Merryweather & Son.

Meetings for the Week.

Mon.—*Medical Soc.*, Lettsomian Lecture at 8.30 p.m.
Royal Geographical Soc., 1, Communication from Mr. Tinné, relating to "Explorations on the River District West of the White Nile." 2, "Journey of Colonel Pelly on the Shores of the Persian Gulf." at 8.30 p.m.
Tues.—*Inst. Civil Engineers*, Discussion on "Cornish Pumping Engines," at 8 p.m.
Thur.—*Antiquaries*, at 8 p.m.
Fri.—*Architectural Assoc.*, Discussion on Reports and Architectural Alliance. Also discussion on Mr. Darbishire's Paper on "Dwellings for the Working Classes."

Miscellanea.

The agent and superintendent of the Indus steam flotilla reports, on the 9th October, that the steamers and barges were actively engaged; five of the former, with attendant barges, having left Kotree with freight within eight days, another being ready to follow on the arrival of the English mail.

The proprietors of the "Great Eastern" have decided to make an effort to raise a further sum of £60,000, and to send the ship on a long voyage (to India or Australia), which, it is hoped, will prove more remunerative than the ruinous trips to New York.

A submarine cable, to connect Bristol and South Wales, has been successfully laid across the Bristol Channel at New Passage, by the British and Irish Magnetic Telegraph Company.

The shares in the Suez Canal Company have fallen to 375f., on account of two causes—first, a call of 50f. per share; and second, the Viceroy of Egypt having reduced the number of forced labourers from 25,000 to 6,000 men.

The manufacture of American watches, commenced within the last ten years in Boston as an experiment, has proved eminently successful. Unable heretofore to compete with the low-priced labour of European workmen, they perfected machinery by the aid of which watch movements are fabricated equal to the hand-made. The continued growth of this branch will diminish the importation of foreign watches, and may at no distant period earn for North America a reputation in this manufacture equal to that she enjoys in the kindred branches of clock-making. Gold and silver watch cases are now produced to a very large extent, chiefly in the cities of Philadelphia, New York, and Newark.

It is stated that the Viceroy of Egypt is importing steam ploughs on so large a scale as to tax the manufacturing capacity of England. He will soon have a capital of £200,000 in steam ploughs on his own estates alone, and is about to form a model farm on a large scale under the direction of an English agriculturist, where the work will be carried on with the most recent improvements used in England.

The foundation stone of a breakwater was laid on the 3rd inst. at the mouth of the river Tees. The breakwater is intended to extend seawards upwards of two miles, and when completed will form an admirable harbour of refuge during the prevalence of those easterly gales which annually rage on the north-east coast, causing immense destruction of valuable shipping property, accompanied with lamentable loss of life.

The Boston *Commercial Bulletin* says of the "Niagara":—This splendid vessel is now at anchor in the stream, and looks well; but she is altogether too deep, as she draws nearly 26 ft. of water—2 ft. more than the "Great Eastern," and 1 ft. more than the famous British iron-clad "Warrior.' Her main-deck ports do not seem to be more than 5 ft. from the water, and consequently, in a seaway, could not be opened with safety to use her best. battery. We have heard that she has not room enough to contain more than two and a-half months' stores for her crew, in consequence of the blunders of those sages in Washington, who designed the alterations in her. She was so deep when she had all the stores on board that some of her coal had to be taken out to lighten her. We have heard that she is bound to the Mediterranean, where she will be of as much use as if she was lying where she is—perhaps less, for here she might be used to protect the city. In the Mediterranean we require swift sloops of war and a gunboat or two, not a ship like the "Niagara."

The "Warrior" is undergoing a thorough examination in dock at Portsmouth. The *Times* says that many improvements have been recently made in the fittings of the vessel. Perhaps the one possessing the greatest novelty is the introduction of "ozone gas" into the engine-room and screw alley. Two small copper reservoirs, holding about a quart imperial measure each, contain a supply of spirituous oil which flows by a pipe, after the manner of a caged bird's water fountain, into a small copper enclosed tray filled with sponge. Through this a stream of atmospheric air is blown by a pipe from a pump (the latter set in motion by a weight and pulley), which, passing out by a discharge pipe at the opposite end of the tray, passes direct to the burners. There it gives out a beautiful white light, with comparatively no heat. An apparatus for the supply of a dozen burners may be carried under the arm. It requires no gasometer, and its use entails no danger to the ship. It emits no smell when burning, nor does the vapour itself, when allowed to escape unburnt from the nozzle of the burner. Its use entails no attention beyond the winding up, once in 24 hours, of the small weight which sets the machinery of the air-pump in motion. Its cost is one-fourth that of the candles served out for use from the paymaster's stores of the ship.

M. Jules Seguin has brought before the Parisian public a project for aerial locomotion between the Place de la Concorde and the Porte de la Muette, on Moreaud's system. According to this arrangement, the balloon will be held captive by means of a steel wire cable, running over vertical pulleys at the point of departure and arrival. These so-called pulleys are really large cylinders or drums on which the rope is wound backwards and forwards by means of a steam engine. To the cable which performs the functions of a locomotive, is fixed a line, which conducts the balloon; this is the general idea of a system on which Mr. Moreaud has experimented with great success, employing small balloons. M. Seguin proposes to carry 250 persons at each trip, from the Place de la Concorde to the Bois de Boulogne, or about 600,000 persons per year.

M. Polonze has laid before the Academy of Sciences, at its last meeting, a memoir on the Imperial Saltpetre Refinery at Lille, from the pen of M. Violette, *Commissaire des Poudres et Saltpetres.* This establishment is unique in France, and reflects great credit on M. Violette, by whom it was designed. It comprises a large storehouse or magazine, capable of containing three millions of kilogrammes of crude saltpetre; a refinery, from which half a million of kilogrammes of purified saltpetre can be turned out annually; a magazine, in which two hundred thousand kilogrammes of pure saltpetre can be stored with ease; and a cooperage, which supplies twelve thousand barrels yearly, in which products of the manufactory are packed. Iron tramroads form the means of communication all through the works. Water is distributed over the entire factory in pipes, through which it descends by its own weight from large tanks over the building. The rain water is collected in a cistern, holding 2,000 hectolitres. The products of combustion from all the furnaces unite in one immense chimney, wherein the draught is considerable. The gases escape at no higher temperature than 100 deg. Cent.; fair evidence of the complete utilization of the heat derived from the combustibles.

Our neighbours in France appear determined to follow up those magnificent schemes of inland communication by water inaugurated by M. Lesseps. Even a more gigantic project than the formation of Paris into a seaport is now said to be seriously contemplated. It is proposed to dig a canal which, starting from Marseilles, will join the Saone at Chalons, and thence form two branches. One of these branches is to be continued to Dunkirk, and the other to St. Naziere. M. Croy has published a pamphlet explaining the details.

One of the new 300-pounder guns intended for experiment on board the gunnery ship "Excellent" was on Monday mounted on its carriage and slide on the wharf at Woolwich for trial, in the presence of Brigadier-Gen. St. George, president, and the other members of the Ordnance Select Committee of Woolwich Arsenal. The breech of the gun is raised or depressed on Lieut. Roche's system. The apparatus is worked by a small pinion working into a rack formed on a hoop encircling the gun, and a quoin is thrust under the breech when a proper adjustment has been made. The trial appeared to be satisfactory, and the gun and fittings are to be forwarded by an early opportunity to Portsmouth. Mr. Parsons' breech-loading 6-pounder gun, which was satisfactorily proved a short time ago at Woolwich, underwent the same day a final trial at the proof-butt in the Royal Arsenal, in the presence of the Select Committee of Ordnance, by firing 100 rounds. The entire test occupied only 52½ minutes, including a delay which took place at the sixth round. The 94 rounds fired from that time were completed in 42 minutes, or one round in 30 seconds. Although, from the rapid firing, the gun at its termination was so hot that the hand could not touch it, the breech-action worked with perfect freedom, and maintained the breech quite gas-tight. Mr. Parsons suggests the adaptation of his plan to guns of larger calibre, as by it the sphere which serves the place of the vent-piece can be made of any size and strength necessary, as it has not to be lifted out of its place in the operation of loading. In a 110-pounder it may be made 800lbs. weight, and it will have corresponding strength. The slot necessary in the Armstrong gun is also dispensed with.

A Glasgow paper announces "for sale, by private bargain, the wonderful organ of James Watt, the illustrious inventor of steam, made by his own hands for his own amusement, in the city of Glasgow, nearly 100 years ago."

The new iron paddle steamer, "Will o' the Wisp," 600 tons, and 180 horse-power, was tried on Saturday, on the Clyde. The builders had engaged to carry 200 tons dead weight at the speed of 17 miles an hour, under a considerable penalty—the owners engaging to pay a premium of the same amount if the vessel exceeded that speed —Mr. Wilkie, engineer, Glasgow, being appointed umpire. With the above cargo the vessel accomplished the distance between the Cloch and Cumbrae Lights in 52 minutes 11 seconds, being over 18 miles an hour; consequently the builders have won the premium. The "Will o' the Wisp" was designed, built, and engined by W. Simons and Co., London Works, Renfrew.

The Admiralty has at last awakened to the importance of providing, at least a few very fast steam frigates calculated to cope with such vessels as the "Alabama." Mr. Reid, Chief Constructor of the Navy, delivered a lecture on "Ships of War," on Tuesday evening, in the hall of the Literary Institute, Greenwich, in the course of which he stated, with the utmost confidence, that the Admiralty was now building a corvette from which the swiftest iron vessel now afloat could not hope to escape, and which would be armed in a most effective manner. It will be remembered that the Mechanics' Magazine has persistently enforced the necessity of constructing high-speed frigates to defend our mercantile marine.

A new method of case-hardening iron has been patented in Germany by M. Martignoni. The process consists in rubbing the surface of the iron, while at a red heat, with the following composition:—5 parts of cow-hoof, reduced to fine shavings; 5 parts of quinquina; 2·5 parts of common sea-salt; 1·5 parts of saltpetre; and 10 parts of coarse black soap. This mixture is formed into a paste, and applied by a roller, on which it is smeared. The iron is subsequently tempered in cold water.

The Queen has added another jewel to her crown, by prohibiting smoking in the palace at Windsor.

Patents for Inventions.

ABRIDGED SPECIFICATIONS OF PATENTS.

The Abridged Specifications of Patents given below are classified, according to the subjects to which the respective inventions refer, in the following Table. By the system of classification adopted, the numerical and chronological order of the specifications is preserved, and combined with all the advantages of a division into classes. It should be understood that these abridgements are prepared exclusively for this Magazine from official copies supplied by the Government, and are therefore the property of the Proprietors of this Magazine. Other Papers are hereby warned not to produce them without an acknowledgement:—

ROADS AND VEHICLES, including railway plant and carriages, saddlery and harness, &c., 918, 923, 926, 946.
SHIPS AND BOATS, including their fittings, 914, 955.
STEAM ENGINES, &c.—*none.*
WARFARE, 49.

899. R. K. PENSON. *Improvements in apparatus used for warming railway carriages.* (A communication.) Dated April 9, 1863.

For the purposes of this invention warmers are placed between the seats of the carriages, and in a position to come under the feet of the passengers. It is preferred that each warmer should consist of a flat tubular chamber, but the section and form of the warmer may be varied. A portion of the funnel, or the chimney of the locomotive engine, is partitioned off so as to produce a compartment at the bottom to intercept part of the steam from the steam cylinders. This compartment has a door or cover at the upper part, which, when open, allows the steam to rise up through the funnel or chimney, and escape, as is usual; but when the door or cover is closed, a portion of the steam is intercepted, and a steam pipe connected to the compartment in the chimney or funnel leads the intercepted portion of the steam to the warming apparatus in the passenger carriages. The warmers contained in the different bodies or compartments of a passenger carriage are connected together by suitable steam pipes, and steam having been conducted into the warming apparatus in that one of the passenger carriages of a train which is next the locomotive engine, circulates through the warming apparatus of that carriage, and then by means of suitable couplings or connections between the carriages the steam is conducted from carriage to carriage, and thence ultimately to the open air. It is preferred to form the couplings or connections in the following manner:—At each end of the warmers of each passenger carriage is a flexible pipe, having a coiled wire to strengthen it, and to maintain its figure. This tube and one end of the coiled wire are fixed to a disc or plate, which has a short length of metal pipe with a flange fixed thereto, and the pipe and plate are supported in position by a wire of other metallic stays. When two carriages are coupled, the two ends of two coupling tubes are brought together, and two pendent or lever clips draw and hold the two ends together, so as to form a continuous passage for the steam to pass from one carriage to the next. *Patent completed.*

900. J. R. BURTON, K.H.A. *A new method of and apparatus for cleansing ships' bottoms.* Dated April 9, 1863.

This invention consists of a semicircular tube, varying from 3 ft. to 6 ft. in length, to be proportioned to the size of the ship, and 2½ ft. to 3½ ft. in width, according to the length of the tube. The depth of this semicircular tube is to be 2 ft. and flat at the top to receive the brush, which should be made of whalebone, and fixed to a wooden frame, and which wooden frame will be fastened on the tube by iron straps with eyes at each end to receive a screw to fasten such straps. By this plan a fresh brush can at any time replace the old one when worn out. When the ships' bottoms are very foul, and require more than a brush to remove the weeds or shells, an iron plate can be screwed on at each end of the machine to act as a scraper to tear all obstructions away. *Patent abandoned.*

901. G. FERRAND. *Certain improvements in apparatus for supplying oil or other liquid lubricant to frictional surfaces.* Dated April 9, 1863.

This invention consists in the employment of a bent or angled tube inside the can, one end being attached to and forming part of the delivery tube or spout, the other end being brought near to the interior surface of the "can," the distance being just sufficient to allow the oil to pass into the aperture of the tube, such aperture being at a point about opposite the point of delivery, so that the liquid only covers the aperture, and allows it to pass down the tube, and to the spout, when the can is partly inverted, as in oiling. The delivery spout is held downwards when a flow of liquid is required, from which it issues in drops, air passing up the spout between the delivery of each drop; or air may be conveyed by a separate tube into the "can." A receiver or channel is arranged near the end of the point of delivery to receive and convey waste drops back again to the can either down the spout or down the air tube. *Patent abandoned.*

902. A. V. NEWTON. *An improved construction of offensive weapon.* (A communication.) Dated April 9, 1863.

This invention consists in the combination with a lance of a revolving many-chambered cylinder (of similar character to that commonly used in revolver firearms) arranged to rotate upon the pole or shaft of a lance by having the said pole or shaft passed directly through it. The many-chambered cylinder is made removeable from the lance, and it is furnished at its rear end with a circular series of ratchet-like teeth corresponding in number with the chambers. The lance, pole, or stock is fitted with a hammer so formed and arranged that, by turning the cylinder upon the axis, the ratchet teeth will force back the hammer in such manner as to permit of its being driven forward again by a suitably applied spring. The hammer when driven forward will strike upon the uppermost of a series of percussion caps, or their equivalent, applied in rear of the several chambers and fire the charge contained therein, the charges of all the chambers being in like manner discharged in regular succession. Fitted to the butt of the pole or shaft is a spike, which can be sheathed by being pushed into the pole or shaft when the weapon is to be carried or u d, and protruded from the butt to enable it to be drive into the ground to hold the weapon in an upright position ready to be quickly laid hold of when required for use. *Patent completed.*

903. G. LOW. *Improved machinery for boring rocks and other hard substances.* Dated April 9, 1863.

This invention relates to a novel construction of boring machinery, whereby the driving of adits and the working of quarries may be greatly expedited. The machinery, which admits of various modifications, may be described as consisting of a frame, in which is mounted one or a series of cylinders, fitted each with a piston attached to a hollow rod, which carries at one end a hollow boring tool. The frame will run on wheels for driving horizontal adits or railway tunnels, and against the face of quarries; or it may be arranged to hang from a chain when driving or sinking perpendicular or inclined shafts. Another form of frame (being a portable one) consists of a pillar or column which can be adjusted betwixt the top and bottom of the adit in any position by the attendant. For one arrangement the working cylinders are set on guide frames, along which they slide by a self-acting worm and screw motion, according to the progress of the boring tool. Each of the cylinder frames is so arranged as to admit of being easily moved by the attendant, either perpendicularly or sideways, and also at any angle in either direction, for the purpose of bringing each of the tools into a position suitable for the nature of the rock strata to be bored. The pistons are worked either by steam conveyed by pipes covered with felt, or by compressed air, or by any other motive gases. *Patent completed.*

904. A. V. NEWTON. *An improvement in stirrups, and in the mode of attaching the same to saddles.* Dated April 9, 1863.

The object of this invention is to cause the point of attachment of the stirrup leather to coincide with the points of fixation of the knees. There is gained thereby—1, fixity of the knee, by this union of the point of suspension of the stirrup and of the point of fixation of the knee, whereby the adherence of the knee (the internal condylus of the femur) to the saddle may be permanent, the knee being continually pressed towards the same point; 2, mobility of the leg on the knee-joint, without inconvenience to the upper parts of the body, as the stirrup leather being of the length of the leg, the stirrup and the foot will have the same centre and the same radius; 3, easy pressure of the knee at a given moment—as the foot does not quit the stirrup, all the movements which would tend to move the foot of the rider from the body of the horse will also remove the stirrup therefrom, but by reason of the centre of action of the foot and the stirrup coinciding, the knees will grip the saddle without any attention on the part of the rider, as this connection will exist whatever may be the movement of the foot; 4, bearing upon the stirrup becomes possible, for the stirrup may be borne upon without the knee being moved and the weight of the body being thrown out of its position; 5, more steady equilibrium, by reason of the pressure upon the stirrup, which will bring the weight of the body to the lowest possible point. *Patent completed.*

905. G. COLOMB. *A process of manufacturing factitious blocks of wood of diversified shades and hues proper for veneering and other purposes.* Dated April 10, 1863.

The patentee claims—1, making blocks of factitious wood with joiners' shavings, by rolling up or heaping together shavings of natural or dyed wood, so as to form bundles or trusses of diversified shades or colours, and mixing, if desired, strips of soft metals or other substances with the said shavings; 2, heaping up together several bundles in a frame, packing them tight together; 3, dipping the same into a bath of hot glue, or any other similar agglutinative substance; 4, pressing the blocks thus obtained sideways by suitable presses when dry enough; 5, drying the blocks in a hot room, through which runs a current of hot air—all as described. *Patent completed.*

906. S. A. COUPERIE. *A semicircular metallic slide, whereby the pole bolt is effectually suppressed, and which can be adapted to every four-wheeled vehicle.* Dated April 10, 1863.

This invention is not described apart from the drawings. *Patent completed.*

907. T. BALDWIN. *Improvements in superheating steam, and in apparatus connected therewith.* Dated April 10, 1863.

In carrying out this invention, for the purpose of superheating the steam before it enters the working cylinders of steam engines, the patentee passes the steam from the boiler through any convenient number of tubes placed in a horizontal, vertical, or inclined position. The said tubes are encased in a flue or chamber, through which the hot gases from a separate furnace to that used for generating the steam in the boiler pass, and are diverted in their passage among the said tubes by plates of metal or fire-clay, so as to cause the heat to be more equally diffused in the said flue or chamber. Or he uses the flue or chamber without the plates of metal or fire-clay when necessary. The hot gases from the separate furnace, after passing among the tubes, are conveyed direct to the chimney by a separate flue; or they may be conveyed into the flue of the boiler as required. He places a damper in such a position as to regulate or prevent the flow of the hot gases from the separate furnace among the tubes, and he places another damper to allow the hot gases to pass to the chimney either along the flue of the boiler, or through a separate flue to the chimney, as may be required. The steam from the boiler on its way to the working cylinder passes through the tubes, and becomes superheated by the action of the hot gases from the separate furnace, thereby requiring less fuel to produce a given mechanical effect than when used without being superheated. He also uses tubes placed one inside the other, the steam passing through the space between the tubes, and the hot gases through the lesser tubes and around the larger ones. He places the tubes in the flue or chamber before named. *Patent completed.*

908. S. SHELMERDINE and J. DRANSFIELD. *Improvements in the ornamentation by printing of felt hats.* Dated April 10, 1863.

In carrying out this invention, the patentees make the felt hat body in the shape of a cone, and then print or stain any desired pattern or ornament on the said cone-shaped body by the block or machine printing operation, printing first one side of the cone and then the other, thus giving the necessary ornamentation, instead of making the hat in sections, or of different portions of fancy materials. They then block the body of the required shape or configuration in the usual way. In order to facilitate the operation of printing the said cone-shaped felt hat, they pass it between two or more revolving rollers to give it two flat surfaces; they then place it in a press, or put it under pressure to give the flat surface a greater amount of solidity. If a press be used, it may be worked either by hand or power, according to the amount of pressure required. They print the said hats either in the self-colour, or stain or dye them previous to printing, as may be found most suitable for ornamentation. *Patent completed.*

909. H. R. SPICER. *Improvements in boxes or cases for the enclosure and preservation of human remains.* Dated April 10, 1863.

This invention consists in the use of glass for the manufacture of boxes or cases of any desired configuration for the enclosure and preservation of human remains. These glass boxes can be hermetically sealed. In some instances, for the further securing or aiding the preservation of the contents, the inventor produces a vacuum or partial vacuum within the said glass boxes by exhaustion. The said glass boxes or cases may be enclosed in an outer case or shell of wood of the ordinary kind. *Patent abandoned.*

910. R. SMITH. *An improved medicated oil for the preservation of metal, wood, or stone.* Dated April 10, 1863.

This invention consists of an improved compound, to be used either alone or in combination with any description of paint, for the preservation of iron or wooden ships, buildings, or articles made of metal, wood, or stone, and is also applicable for the renovating of oil paintings and paint work, and is composed of the following ingredients:—The patentee takes, say, one gallon of any description of oil, and a like quantity of water, to which he adds about 2 lbs. of saltpetre, salt, or soda, either mixed or separate. If the compound is intended for the preservation of stone, he adds about 2 lbs. of soluble sulphur. *Patent completed.*

911. J. WIGHTMAN and C. DENING. *Improvements in horse rakes.* Dated April 10, 1863.

This invention consists in making the tines of such rakes of tubular or hollow form, whereby the rake is rendered much lighter in draught; it is also easier to lift when working. *Patent abandoned.*

912. J. GIMSON. *Improvements in screw-cutting lathes.* Dated April 10, 1863.

This invention consists in so constructing, fitting, and applying parts to such lathes that a tool or tools is or are applied to the operation of cutting the thread or threads of screws while the screw under operation is being rotated in either direction; that is to say, the screw will be cut by a tool or tools actuated and advancing in the ordinary manner, as also (while such ordinary tool is being run backwards, and the screw under operation is rotated in the opposite direction) by another tool or tools thrown in during the time the first-named tool or tools is or are out of action; thus the operation of cutting the screw may be said to be a continuous operation; and the time in running back the saddle is not lost, as in the ordinary manner. *Patent abandoned.*

913. H. W. RIPLEY. *Improvements in machinery for preparing and printing wool and other fibres.* (A communication.) Dated April 10, 1863.

This invention consists in combining a gill box or gill mechanism with printing machinery, in order that an even sliver or web may be produced, and then printed by the combined machinery. It has before been proposed to print slivers and webs of wool or other fibre with parallel transverse lines or devices, and then, after printing, to subject the printed fabrics to a process of drawing before spinning, as to cause the printed fibres to slide amongst themselves, and thus to extend or shade off the printed lines or devices. The present invention consists in combining the gill machinery used in preparing or producing an even web or sliver of wool or other fibres with a printing machine, so that the sheet or web of fibres may at once pass from the preparing gill machinery ink, and be acted on by the roller printing machine, without requiring to be made into rolls, or be handled and conveyed between one machine and the other. *Patent completed.*

914. H. CAUDWELL. *Improvements in the construction of vessels of war, part of which improvements is applicable to fortifications.* Dated April 10, 1863.

This invention is not described apart from the drawings. *Patent completed.*

915. F. VERSMANN. *Improvements in moulding machines.* Dated April 11, 1863.

The patentee claims—1, the method by which a certain quantity of the material introduced into the machine is delivered in any form or shape required by a screw revolving in the interior of a hollow cylinder, with an intermittent action, or any other arrangement producing the same effect, such as a plunger or piston, or a reciprocating blade or cylinder, with a semi-rotary piston, as described; 2, the peculiar method of cutting off the said material into given lengths by means of the reciprocating cutters or knives mounted in a frame; 3, the intermittent action, and the mode described of obtaining the same, and communicating it to the endless bands for assisting the delivery of the material, and alternately to the feeding screw or other feeding power, and the cutting-off frame. He does not confine himself to the method described, but he claims all such other methods as may accomplish the same result. *Patent abandoned.*

916. J. LOCKWOOD. *Improvements in steam boiler and other furnaces.* Dated April 11, 1863.

This invention consists in having the bridge formed hollow with a grating towards the fire bed, and open to the ashpit, and a swing door placed behind the grating, capable of being operated by a rod from the front of the furnace, by which it may be closed against the openings of the grating, or removed therefrom, as required, to admit atmospheric air, whereby smoke will be consumed. *Patent completed.*

917. D. MYERS. *Improvements in fire bars or furnace grids.* Dated April 11, 1863.

In carrying out this invention, the patentee makes the cross bars of a waved, zig-zag, or corrugated shape, either circular or angular, with a groove on the upper surface to catch or collect small dust from the ashes from the fuel, which dust being a non-conductor of heat, preserves the bars from being soon consumed or burnt, and also prevents the coals from clinkering. In one arrangement he casts the side bars and cross bars together, so as to form a framework or grid for the furnace, and makes the side bars either straight or corrugated; but in either case there is a groove or recess on the surface of the side and cross bars for the collection of the dust or ashes. This plan enables him to make the bars much lighter than the usual form, as well as economizing fuel and metal, and preventing the clinkering of the coals. The corrugated or zig-zag surface of the bars, by presenting the greatest amount of surface to the action of the atmosphere, keeps them cool. *Patent completed.*

918. W. SAMUEL. *Improvements in, or applicable to, railway carriages, to mitigate or lessen the effects of collision to passengers.* Dated April 11, 1863.

This invention consists—1, in constructing carriages with a larger number of transverse partitions therein than there are in those at present in use, and between such partitions placing across the carriages one row of seats only, so that passengers shall not set opposite to each other, and there shall not be danger from one person being thrown against another at the instant of collision; 2, in placing round railway carriages, of whatever construction, at or about the height of a man's shoulder when he is sitting on the seats of such carriages, and for a short distance both above and below such height, air cushions, made of india rubber, or other flexible material, assisted by metal or other springs, or by padding or stuffing of any kind. *Patent abandoned.*

919. J. FARRAR. *Improvements in machinery or apparatus for twisting or doubling yarns of wool or other fibrous substances.* Dated April 11, 1863.

This invention relates to machinery having rotary spindles, and the improvements consist—1, in having bushes to the spindle rails or copping rails, which project upward sufficient to pass through the bobbins which are placed thereon. The spindles pass through these bushes, and are thereby held steady. 2, The improvements consist in having a ring fixed on the arms of each flyer, to prevent expansion thereof when run at high speeds. The "tweezles" may be fixed in this ring, or be formed on the arms as at present. *Patent abandoned.*

920. W. CLARK. *Improvements in separating ores from their gangues, and in apparatus for the same.* (A communication.) Dated April 11, 1863.

The patentee claims—1, the improved apparatus for classifying ores, consisting of a series of screens or sieves of different degrees of coarseness, serving to collect the particles of the ore in uniform sizes of grain, as described. 2, the several modifications of the above-mentioned apparatus as represented in the drawings; 3, the improved atmospheric separating apparatus in which a forced current of air is employed for acting on ores of different gravity, although of same size, in order to separate the quartz from the metal particles as described; 4, the improved apparatus for treating schlammes, the sieves having a to-and-fro motion imparted in the manner described; 5, the arrangement of cup chain for supplying the ore in a continuous manner into the hoppers of the several apparatus, all as applied, described, and represented in the drawings. *Patent completed.*

921. P. P. BALY. *Improvements in constructing breakwaters, piers, sea walls, and other similar structures.* Dated April 11, 1863.

In constructing breakwaters, piers, and other similar structures having two parallel or nearly parallel faces, or faces inclined to one another, the patentee employs at intervals transverse frames constructed of cast or wrought iron bars, or rods, or plates. These frames are, by preference, triangular in form, and are, if necessary, strengthened interiorly by other bars, or rods, or plates dividing the frame up into a number of small triangles. The base of the frames is suitably secured to the bottom, or is supported thereon, upon screw or other piles or chairs of iron, wood, or stone, upon a bank of stone, or other made foundation; or the frames and plating attached to them may be supported by the plating resting upon the ground, or upon a made foundation. To the sides of the frames cast or wrought iron frames are fixed to form the two parallel or nearly parallel fac s, or faces inclined to one another, of the structure. These plates are corrugated or arranged in ridge and furrow; the corrugations or ridges run horizontally in, and they serve to give great rigidity to, the structure in this direction. These corrugated plates, or plates arranged in ridge or furrow, may be of wrought or cast iron, and connected togther and to the frames by bolts and nuts, screws, rivets, clips, or in any other suitable manner. In joining the plates together endways, it is preferred to make those of one row break joint with those of the next row. In a direction at right angles to the corrugations or ridges, a certain amount of stiffness is given by the transverse frames before mentioned, and these are assisted by means of bars placed on the exterior of the plating at distances apart equal to the distances between the transverse frames. These bars are placed opposite and parallel to the sides of the frames, and are securely fixed to the top of each corrugation or ridge of the plating, which they cross, as are also the exterior bars of the transverse frames above described. Thus it will be seen that the sides of the transverse frame acting with the corrugated or ridged plating attached to it, and with the exterior bar parallel thereto, form together a framed girder of great strength. In order to give additional stiffness to the corrugated or ridged plates, pairs of bars or single bars may be made to cross, and be fixed to the corrugations or ridges upon the exterior and interior of the plating, and intermediate between the frames above described. *Patent completed.*

922. A. F. MACLURE. *Improvements in looms for weaving figured fabrics.* Dated April 11, 1863.

This invention relates to the arrangement and construction of certain parts of mechanical details of looms, so as to obtain by means of a positive movement a great variety of patterns in the fabrics produced. Under one modification or system of arrangement for actuating the heddles in the required sequential order, two levers are centred upon a stud carried in the loom framing. These levers extend towards the front of the loom, and are slotted at the central parts so as to admit of the driving shaft passing through them, and of their reciprocatory movement in a vertical direction. These levers are actuated by two cams on the driving shaft, which act on pulleys fitted to the levers, and cause them to rise and fall alternately. The front ends of the levers are connected by vertical links to two knife-edged lifting bars which are arranged beneath. These levers traverse up and down in guides which are formed in a pair of standards fixed to the floor, and extending parallel with the loom framing. On the wiper shaft of the loom is fitted a cam which gives a slight vertical movement to a rod, T-shaped at its upper extremity, and carrying therein a series of pins which extend through the T-piece on both sides. The movement of this rod up and down brings the row of pins alternately opposite two rows of holes formed in a small rotary barrel, similar to the barrel of a jacquard machine. This barrel moves in unison with the shedding action of the loom, and carries with it an endless chain of cards, perforated to produce the required pattern. Each pin in the T-shaped rod is opposite one of the long vertical rods, which are connected to the heddle levers. These rods are kept in one direction by means of helical springs, so long as the pins in the T-shaped rod enter the holes formed in the endless chain of cards; but when the solid card intervenes, the opposite end of the T-shaped rod pushes the contiguous rod back and this brings one of the hooks which are formed on the rod under the edge of one or other of the lifters. In this way, by the proper arrangement of the cards, the heddles may be actuated in any required sequence, so as to produce a great variety of weaving effects. In connection with these mechanical arrangements is one for causing the shuttles to be operated in any desired order, for the purpose of varying the colours of the figures or other ornamental effect. *Patent completed.*

923. C. A. COLLINS. *An improved method and apparatus for loading carts and waggons with hay, straw, and other similar products.* Dated April 11, 1863.

This invention consists in an apparatus or machine on wheels which is attached to the back of a cart, and is set in motion by being drawn after the cart. Such machine includes a combination of two endless bands; each of such endless bands work on pairs of horizontal rollers or wheels connected by an axis, the hindermost band being carried in a direction opposite to that of the cart wheels, while the foremost band works in the same direction as that of the cart wheels. Each band is carried within a short distance of the ground, the hindermost band being the nearer to the ground, and as the incline is drawn after the cart, such hindermost band being caused to move in a direction contrary to that of the cart, collects the hay upon the ground over which such bands passes, and brings the hay into contact with the foremost band, and the hay is thereupon elevated and carried on to the cart. *Patent completed.*

924. J. RAMSBOTTOM. *Improvements in machinery for hammering, rolling, and shaping metals.* Dated April 13, 1863.

This invention consists—1, in certain improvements in or applicable to duplex or compound steam hammers, having two or more hammer blocks moving in opposite directions towards the metal to be operated upon, in such wise that the acting forces may counteract each other, and so avoid in most cases the use of an anvil. 2, in an improved combination of machinery for rolling and shaping metals. The invention cannot be described without reference to the drawings. *Patent completed.*

925. J. GILL. *Improvements in printing machinery.* Dated April 13, 1863.

This invention is not described apart from the drawings. *Patent completed.*

926. A. ROLFE. *Improvements in means or apparatus for propelling carriages on railways, tramways, or on common roads.* Dated April 13, 1863.

In carrying out this invention, the inventor arranges on a carriage, suitably constructed for the purpose, a wheel or wheels of proper size, which is or are mounted on frictionless bearings, and actuated (by preference) by men working the handles or cranks attached to the said wheel or wheels, though steam or air engines or other means may be employed for this purpose. These fly-wheels are connected by means of endless bands or straps with a series of one or more wheels, suitably mounted on the framing carrying the fly wheel or wheels, and are finally connected (by means of fast and loose pulleys on the axle) with the wheels running on the road, and to which the power is thereby imparted. In working the apparatus, when the time arrives for stopping the train or carriages, the strap connected with the driving wheel is shifted on to a loose pulley from the pulley which actuates these wheels, and when there, instead of the men or other power working the levers stopping the fly-wheel, they continue it at work, and the power so obtained is accumulated by the fly-wheel until required when starting the train, when, on the strap being shifted to the fast pulley, the carriage will be at once propelled forwards. When it is required to stop the carriage, brakes are applied in the ordinary manner, or they may be so adapted as to cause the power wasted in the act of "braking" to be transmitted by suitable gearing to the fly wheel or wheels. When required to reverse the carriage, the fly-wheel may be stopped, and the fly-wheels reversed by working them backwards; or the wheels may be continued in the same direction, and the motion may be reversed by having crossed straps working on fast and loose pulleys, so that the pulleys work different ways on the straps, being shifted as is well understood. *Patent abandoned.*

927. R. LEGGETT and R. GITTUS. *Improvements in the construction of machinery or apparatus for cutting chaff and other agricultural produce.* Dated April 13, 1863.

The first part of this invention consists in the adaptation of moveable knives, in place of fixed ones, for the purpose of producing a drawing cut throughout the stroke or passage of the knives. The second part of the invention relates to the construction of the pressure plate, which the patentees term a "duplex" pressure plate, one portion of it moving vertically in the ordinary way, but the other portion having a circular motion corresponding with the circumference of the top feeding roller, to which it closely fits, in order that the space between the vertical portion of the pressure plate and the said roller shall always be completely filled up, so as to prevent any choking of the material to be cut. The third part of the invention relates to the mode of constructing the feed rollers. Instead of these rollers being notched or grooved longitudinally, they have deep ribs cast on them in the direction of their circumferences. The ribs traverse the circumference of the said rollers, not at right angles to their axes, but more or less inclined thereto—the inclination of the ribs of the top roller being one way, and those of the bottom roller the other way. This difference of direction of the ribs on the rollers has the effect of straightening out the separate straws or fibres of the material to be cut, when lying crosswise, sending them through the mouth of the machine at right angles to the plane in which the knives revolve. *Patent completed.*

928. J. LARK. *Improvements in the manufacture of artificial fuel and cement.* Dated April 13, 1863.

In order to produce artificial fuel, the inventor takes lime-stones, chalk, cement-stones, gypsum, slate, or other stone which becomes porous when calcined; or clay may be employed; and having calcined the same, he boils or mixes the material which should then be in lumps of suitable size for fuel, with gas-tar, pitch, bitumen, or bituminous matter. In this manner the lumps are thoroughly saturated with the material, which is kept liquid by sufficient heat. He also sometimes employs a small quantity of paraffin, naphtha, resinous and fatty and oily matters, to increase the inflammability of the fuel. After fuel thus prepared is burnt, the residue when ground makes a good cement suitable to Roman cement. *Patent abandoned.*

929. R. REEVES. *Improvements in the manufacture of liquid manure drills.* Dated April 13, 1863.

According to this invention, in place of employing a number of separate cups or dippers attached to a wheel, the patentee casts the cups or dippers in one piece with the wheel. By this means the cups or dippers cannot possibly get out of their proper position as they now sometimes do, and, in addition, the wheel, together with the cups or dippers, can be made at a less cost than heretofore. *Patent completed.*

930. R. NEWTON. *Improvements in machinery for separating and straightening the fibres of silk waste and other fibrous substances.* Dated April 13, 1863.

This invention consists in mounting in a moveable rotating frame two or more cylinders armed with teeth or combs, which are filled with the fibrous material from the feeding-in apparatus in the usual manner. On the axle of each of the comb cylinders is mounted a toothed wheel, which, when the cylinder is brought into a position to be filled, is put in gear with driving gear attached to the same. Upon the machine being set in motion, and the fibres fed in, the comb cylinder is made to rotate, and gradually fill the combs with fibres. When filled, the cylinder must be removed, and a fresh cylinder put in its place. To effect this, the rotating frame in which the comb cylinders are mounted is drawn back a short distance, and then made to rotate on its axis, so as to bring away the filled cylinder, and put in its place an empty one. The rotating frame is then pushed back, so as to bring the toothed wheel on the axle of the empty cylinder into gear with the driving wheels of the machine. The rotating frame is kept steady by causing a projecting pin thereon to take into a corresponding socket on some convenient part of the stationary framing. *Patent completed.*

931. M. MYERS. *Improvements in the construction of trunks, portmanteaus, and boxes.* Dated April 13, 1863.

In carrying out this invention, the patentee forms the trunk, portmanteau, or box of wicker or basket work, wood, leather, or other light material, and covers the exterior with leather, leather cloth, or other waterproof fabric, the interior being lined in the ordinary manner. He makes the top or lid of the box with a collapsible or bellows-formed receptacle, the entrance to which is through an aperture exposed when the lid is thrown back or opened. He also makes baskets, portmanteaus, or boxes with a plain lid or top, and makes the upper half of the box collapsible. He arranges springs in the interior of the collapsible receptacle in such manner that they shall open or raise them to their utmost limit ready for being packed. When the box is closed, the collapsible receptacle may be compressed by means of the straps. *Patent completed.*

932. T. MALLINSON and P. WILLIAMS. *Improvements in machinery for opening, cleaning, carding, and grinding or sharpening cards used in preparing cotton and other fibrous materials.* Dated April 13, 1863.

The object of this invention applies to machines for opening and cleaning cotton and other fibrous materials, and also to carding engines, and consists in the use in such machines of a fluted feeding roller, having its flutes formed into the shape of ratchet teeth, the inclination of the flutes being in a direction opposite to that of the motion of the "beaters" or the teeth of the cylinder or "openers" or blowers or the lickers-in or cylinder of carding engines, at the time when such beaters or teeth are passing the feeding roller. A roller with pointed teeth, or an ordinary fluted roller, is used in combination with the ratchet fluted feeding roller. The second part of the invention is also applicable both to "openers" or blowers, and to carding engines, and consists in the use of a series of bars, which are curved to correspond to the convex sur-

face or cylinder circumscribed by the beaters or the points of the teeth of the cylinder, or of the licker-in, which takes the fibrous material from the feed rollers. These bars are arranged together with spaces between them to form a grid, and the concave edges of the bars are serrated, and the whole grid is arranged so that a reciprocating motion can be imparted to it in a direction parallel to the axis of the beater, toothed cylinder, or licker-in. The third part of the invention relates to carding engines, and consists in arranging a partition or cover between the ends of the card rollers, clearers, or cylinders, and the "bends" or sides of the engine, to protect the bearings of the card rollers or clearers from "fly" driven out by the current of air produced by the card cylinder; these partitions or covers are adjustable to the axis of the rollers and clearers, as their position is changed in adjusting them to the wear of the cards. The fourth part of the invention relates to the doffing motion of carding engines, and consists in the following arrangement and combination of mechanism:—On the end of the oscillating shaft carrying a peculiarly curved doffer comb, an arm is secured, having a slot in it the lengthway of the arm, in which slot an adjustable stud or pin is secured, which fits so as to slide freely in another slot lengthway in one end of a lever placed immediately in front of the arm; the fulcrum of the lever is upon a stud secured in the framing, and at the other end of the lever another slot is formed in which a crank pin or eccentric works, which is attached to a pulley carried in suitable bearings, which pulley is driven by a band from any convenient part of the engine. By this means the lever has oscillations imparted to it which are transmitted by means of the stud to the arm of the oscillating shaft. The stud is adjustable, so that the length of the oscillations of the comb shaft can be varied when required. *Patent completed.*

933. J. NASMITH and S. THORNTON. *Improvements in machinery for carding cotton and other fibrous substances.* Dated April 14, 1863.

The object of this invention is to strip the fleece of fibres from the doffer of the carding engine; and the nature of the invention consists in certain improved modes of working the stripping comb, so that the teeth of the comb shall clear the doffer at the up stroke. In performing the invention, the inventors make use of a comb of the ordinary construction fixed to arms projecting from a tube, or partial tube, to which two or more straps or bands are attached, parts of which are provided with adjusting screws and nuts, and the others with springs; these straps or bands form the fulcrum, and limit the range of the comb, which is worked by eccentrics or cams on a cross shaft. *Patent abandoned.*

934. G. BERRY. *Improvements in locks.* Dated April 14, 1863.

This invention has reference to that description of lock in which a number of sliding guards pass through notches in a locking plate also having notches in it. The first improvement consists in cutting notches on the sliding guards at right angles to the notches which have to pass the locking plate. The inventor then places an immoveable mask or partition in each of the first-named notches, and these masks or partitions consist of rings placed in a barrel, or a plain plate placed in a box when the motion intended to open the box is lineal instead of circular. The result of this arrangement is that the notches in the guards cannot be got at by any instrument whatever, as they are placed in a line parallel to the part acted upon by the key, but separated by masks or partitions. The second improvement consists in cutting the sliding guards into two parts, in such a manner that, if force be applied to one part, that force will be communicated to the other, and both will move in the same direction. Those parts through which force and motion are communicated to the other parts are called media; and the result is, that no vibration of those parts which indirectly receive force and motion is communicated to the key or any instrument applied to open the lock. *Patent abandoned.*

935. G. T. SMITH. *Improvements in metallic window-shutters.* Dated April 14, 1863.

This invention is not described apart from the drawings. *Patent completed.*

936. W. and J. KEATS. *Improvements in the manufacture of boots, shoes, or other coverings for the feet.* Dated April 14, 1863.

In manufacturing boots, shoes, or other coverings for the feet according to this invention, the edge of the sole has a strip cut from its under side all round its edge, so as to leave all round the upper edge of the sole a strip of less thickness than the rest of the sole; to this thin strip, the edge of the upper, previously cut to the required shape, is sewn, the outer face of the upper being towards the outer face of the sole. The upper and sole are then turned inside out, and the boot or other covering for the feet may then be finished as though the upper had been connected to the sole in the usual way. In addition to the sole being cut as above described, so as to leave a thin strip around its edge, the patentees prefer to enlarge the strip by cutting with a suitable tool a slit into the edge of the sole, just below the bottom or under side of the strip. In constructing boots, shoes, or other coverings for the feet, when a welt is employed, they stitch together all round their edges the insole, the welt, and the upper, the under side of the insole and the outer face of the upper being at that time towards each other, and the welt being between the two. The upper and the insole are then turned inside out, thus causing the welt to project outwards from the insole; the welt may then be connected by stitching or otherwise to a bottom or outer sole formed to the shape of the last, thereby rendering it unnecessary to shape the welt until the said parts are connected. In order to facilitate the parts being turned inside out, they should—except when very thin leather is used—be wetted previous to being turned. *Patent completed.*

937. J. COMBE and J. H. SMALPAGE. *Improvements in the action and arrangement of machines for winding cops, in the construction and arrangement of banks for holding cops for warping purposes, in the formation of shuttles for receiving cops, and for apparatus for packing and securing cops in shuttles; one part of which improvements, consisting of a spring clutch, is applicable to machines in general.* Dated April 14, 1863.

We cannot here give space to the details of this invention. *Patent completed.*

938. J. KEATS and W. S. CLARK. *Improvements in sewing machines.* Dated April 14, 1863.

The patentees claim—1, the combination of apparatus employed; 2, employing a shuttle in a sewing machine, to work in combination with a hook, for the purpose of producing a lock stitch with two threads; 3, placing the shuttle and shuttle race of sewing machines above the table or surface on which the material to be sewed rests; 4, the arrangement of apparatus described for operating a hook, a shuttle, and a feeder from eccentrics in one needle box; 5, the arrangement of apparatus described for dividing the loop of thread that is drawn up by the hook, and for spreading the loop over the shuttle; 6, the arrangement of apparatus described for supplying the thread to the hook; 7, the arrangement of apparatus described for shortening or lengthening the stitch, and for feeding the work at any angle. *Patent completed.*

939. H. TRAPNELL. *Improvements in vent pegs.* Dated April 14, 1863.

This invention consists in making such vent pegs in the form of a metal tube, provided with an ordinary cock, and having a screw thread formed on the lower end, so as to enable the vent peg to be screwed into the barrel or receptacle in place of being driven therein in the ordinary manner. By turning the plug of the cock, the entrance of the air can be regulated, and more readily shut off, than with the ordinary vent peg. The top of the vent peg or tube may be closed, if intended to be driven into the cask by a mallet or hammer, and is slightly expanded and provided with lateral apertures for the entrance of the air or the escape of gases from the cask or receptacle, according to the purpose to which it is applied. *Patent abandoned.*

940. R. A. BROOMAN. *Improvements in hardening and colouring gypseous limestone and sand and calcareous stones.* (A communication.) Dated April 14, 1863.

In hardening gypseous lime-stone, the inventor first reduces the pieces of stone to artistic dimensions, such as balustrades, friezes, columns, &c. He then dries them in a stove heated to a certain temperature. After removal from the stove the pieces of stone are placed in a bath containing a mineral solution. The bath may be composed of lime water, sulphate of iron, cyanides, alumina, potass, soda, or vegetable substances perfectly combined with minerals, or substances obtained from alkaline matters. For colouring, recourse is had to a chemical operation, whereby the inventor obtains a transformation of colours, by making one solution to chemically succeed another. *Patent completed.*

941. R. A. BROOMAN. *Improvements in apparatus for burning light and heavy mineral and vegetable oils.* (A communication.) Dated April 14, 1863.

In lamps with a side supply cistern, the inventor uses a wick carrier tube, and surrounds it by a concentric tube, space being left between the two for holding the wick, and a supply to the same; a plate or ring, with an air passage through the centre, closes the bottom of both tubes. He prefers to use a button to spread the flame; this button is carried on a rod worked by a pinion or projecting spindle, while another spindle is fitted for raising and lowering the wick; a deflecting cone, the edges of which are turned up to hold the chimney, or chimney and globe, slides up and down the outer tube; the top of the cone should be set on a level with the top of the burner. An inclined tube forms a communication between the annular chamber formed between the wick holder tube and that which surrounds it and the bottom of the supply cistern. The level of the supply in the cistern should be in a line with the top of the burner, or a little below it, according to the density of the oil, and the bottom thereof should be on a level with the inclined conducting tube. To maintain the level in the supply cistern, it is formed with a inner box or case which holds the oil, which flows out through a thimble on the pottom thereof, closed by a moveable valve; this valve opens as soon as the box is placed in the outer case. As the level lowers, so the oil flows out from the inner box. The thimble is hollowed in front to the exact height to which the oil is to rise to the burner, so that when the oil becomes consumed at the burner, the air entering the inner box allows a sufficient quantity of oil to run out and rise to the level of the burner. He places a bridge above the entrance into the inclined conducting pipe to prevent the oil bubbling up at the burner. *Patent completed.*

942. J. SMITH. *Improvements in furnaces and boilers for the generation of steam, partly applicable also for other purposes.* Dated April 14, 1863.

In constructing a furnace according to this invention, the patentee makes each alternate fire bar moveable, and forms these inner bars at their inner or back ends with a curved notch, which rests upon a fixed bearing bar, and their outer ends with rack teeth situated in an angular direction, and resting upon and taking into corresponding teeth or segments formed with or fixed upon a bearing bar capable of partial revolution. This bearing bar may either be moved or turned at intervals by hand, or otherwise by means of steam or other power; and when turned or moved as required, will, by means of the toothed segments or pinions referred to, draw forward the racks or bars, and by so doing will (owing to the inclined position of the racks) cause the front ends of the bars to mount or be raised, while at the same time the curved notches at the back, by passing over the fixed bearing bar, will, in like manner, raise the inner or back ends of the bars, thus breaking up any clinker that may be formed upon or between the bars. Bars formed as described are applicable to furnaces for various purposes. The second part of the invention is applicable to locomotive and other similar types of boiler, and consists in dividing the furnace or fire box part thereof horizontally into two portions by means of a water space, situate above the fire grate, a little below the level of the lowest row of tubes, passing through the body of the boiler. The third part of the invention is an improvement in the fusible plug made use of to prevent danger or injury to boilers by deficiency of water. It consists in forming the body of the plug (which has usually been made in one piece screwed direct into the crown of the boiler furnace) in two parts, so that the one part containing the plug may at any time be removed without disturbing the part which is screwed into the boiler. Lastly, he forms that part of the plug which is intended to be blown out by the fusion of the soft holding metal, and the hole in which it is placed, in such manner as to present a greatly increased resistance to the blowing out of the plug by pressure alone. He effects this either by cutting grooves or screw threads in the hole, and similar grooves or threads in or upon the blow-out piece, and running the fusible metal between, so that the whole depth of the fusible metal must be sheared for pressure alone to have the effect referred to. *Patent completed.*

943. J. LEACH. *An improved machine or apparatus for washing, squeezing, mangling, and churning.* Dated April 15, 1863.

In carrying out this invention, the patentee makes use of a barrel or other suitably formed vessel for containing the water and clothes or other articles to be operated upon. This vessel is formed or fitted with trunnions working in suitable bearings (carried by the framing of the machine), so as to be capable of being revolved end over end, and is closed by means of a cover held down by pressure screws which force it against an india-rubber or other partially yeilding packing, so as as to produce a water-tight joint. The pressure screws whereby the cover is held down pass through a frame, which is entirely removeable from the barrel or vessel, leaving no projections above its top, thus affording every facility for the introduction and removal of the clothes or other articles treated. To the interior surface of the barrel or other vessel, at suitable intervals apart, are fixed circular or other conveniently shaped rubbers formed with grooves to give increased surface for acting upon and turning the clothes or other articles to be treated. The inner side of the cover and of the bottom of the vessel are likewise provided with projecting, grooved, or corrugated surfaces or discs, and a grooved or corrugated tilting-board is attached to the interior of the vessel, extending partly across it, at or about the centre of its vertical length. In addition to the foregoing—which consitute the fixed arrangements of the interior of the barrel or vessel—he makes use also within the vessel of a loose or moveable piece formed, by preference, in the shape of an oblate spheroid (but which may be of any other convenient form), the specific gravity of which is such as will cause it to sink in the water or other washing liquid employed, and which is provided with corrugations or projections, so that, by the revolution of the barrel or vessel, it becomes to some extent entangled with the clothes or other articles contained therein, carrying them against and between the rubbers until, being caught by the tilting-board, it, with the clothes or other articles, is carried upwards until, in the course of the revolution, it falls from the tilting-board, and is again caught and carried up as before. In this way the clothes with the moveable piece (which is termed a "dolly") are at each revolution precipitated through the liquid to the bottom of the vessel, thus causing a thorough washing and sluicing, whereby the clothes or other articles are effectually cleansed. The squeezing and mangling are effected by rollers suitably arranged. *Patent completed.*

944. E. P. COLQUHOUN and J. P. FERRIS. *Improvements in fire bars for the furnaces of steam boilers and fire grates.* Dated April 15, 1863.

These fire bars are supported near their centre on two bearing bars partially revolving on their axes. The fire bars on their upper surface are considerably curved to give strength at the point mostly required. On the under side there is cast on the bars, a pin or tougue, fitting into holes formed on the bearing bars, which serve to keep the fire bars in position, and form the draught or air spaces. One half the required number of fire bars necessary to form one tier or range in a furnace are carried by one bearing bar and the remaining half by the other placed in juxtaposition. The fire bars are so packed in the bearing bars that a space sufficient for a fire bar is left between each, so that when the two bearing bars with their allotted number of fire bars are arranged in their proper position, the fire bars carried by each bearing bar dove-tail into each other, and form the furnace, with the necessary width of air space between each fire bar. Cast on the side of each bearing bar are teeth, so that when one bearing bar supporting one half of one range of bars is moved, the bearing bar in juxtaposition, and supporting the other half of the same range of bars, moves in an opposite direction, causing an extensive lift or upward motion to be given to all the fire bars; but while the ends of one half of the number of the fire bars are being raised, the ends of the other half are descending by the side of the uplifted section. *Patent abandoned.*

945. T. GRAY. *Improvements in preparing and bleaching flax, hemp, and other vegetable fibres, by which a brilliant lustre is imparted to those substances, and the fibres are separated.* Dated April 15, 1863.

This invention consists in a method or process of treatment whereby the fibres are so prepared and bleached, that they acquire a brilliant lustre, besides becoming separated and thus fitted for spinning and for other purposes. The flax, hemp, or other vegetable fibre is laid or boiled in soda-ash liquor, or other alkali, for three or four hours; the material is then rinsed and dipped in sulphuric acid water, and, after being slightly drained, is placed in bleaching liquor for about an hour, then rinsed and drained; and afterwards dipped or placed in weak acid water for a few minutes; it is then taken out and slightly drained, so as to leave it still impregnated with the acid; it is then dipped or laid in soap-suds, made from soap in which fat and oil form the chief ingredients. After being rinsed in cold water it is hung up till dry, and is then fit for use. *Patent completed.*

946. W. CLARK. *Improvements in apparatus for the transport of goods.* (A communication.) Dated April 15, 1863.

This apparatus consists of a carriage or platform, which may be constructed of iron, and is furnished at the upper part with small rollers running on rails, which extend in all directions throughout the storehouses, and wherever the merchandize is to be conveyed to, especially along quays. These rails are made portable, and possess the advantage of only occupying the way for a few minutes until the loading is completed, when they are at once removed without trouble or expense. These rails consist of a kind of ladder, the cross bars of which are furnished with iron hooks to prevent the sides from opening, and so keep the rails at an invariable width apart. *Patent abandoned.*

947. H. A. BONNEVILLE. *Improvements in the construction of gas burners.* (A communication.) Dated April 15, 1863.

The patentee claims the construction of gas burners by means of which the combustion of the gas operates without pressure by the holes of a reservoir placed above the tube which regulates the supply. *Patent completed.*

948. A. MARRIOTT. *Improvements in boilers for heating buildings, and in regulators for the same.* Dated April 15, 1863.

In carrying out this invention, the patentee constructs the boiler with an annular water space at the top and bottom, these two water spaces being connected together by vertical tubes. The flow pipe is connected to the upper annular water space, and the return pipe to the lower annular water space. The grate is placed in the interior of the lower annular water space, and is mounted on pivots capable of being tilted by means of a lever outside, so as to empty the contents into the ash-pan. Above the upper annular water space is an annular smoke-box, one side of which is connected to the chimney or flue, and the opposite side to the central fire space, so that the heat and smoke are compelled to pass round the upper annular water space, instead of passing directly to the chimney or flue. The ash-pan is enclosed, air being admitted or shut off by means of a damper, which is opened or closed by a regulator constructed as follows:—In connection with the flow pipe, close to its junction with the upper annular water space, is placed a bulb or hollow sphere of cast iron or other metal, and inside this hollow sphere is placed another hollow sphere of smaller diameter, so that as the hot water passes along the pipe, it circulates freely round the inner sphere, and communicates its heat thereto. The lower side of the inner sphere is connected by a metallic pipe to an elastic tube, closed at the bottom, and attached to the damper by a screwed rod and swivel. The upper part of the inner sphere is also furnished with a pipe, which passes upwards through the outer sphere, where it is closed by a screw cap. Mercury is poured into the inner tube through the last-mentioned pipe, filling the sphere and elastic tube, and the cap is replaced. It will now be evident that, as the temperature of the water increases, it will cause the mercury to expand, and lengthen the elastic tube, and thus cause the rod to close the damper; and as the water cools, the mercury contracts, and allows the elastic tube to open the damper and admit air to the fire. *Patent completed.*

949. W. SPENCE. *Improvements in the manufacture of gunpowder.* (A communication.) Dated April 15, 1863.

The first kind of powder made according to this invention, and which is suitable for ordnance, is composed of the following ingredients, in or about the following proportions, and the process is as follows:—The patentee puts into a cooking or other similar vessel 38 parts in weight of water, and two parts in weight of finely pulverized charcoal, which are to be thoroughly boiled together; he then adds 20 parts in weight of chlorate of potash, and 6 parts in weight of a mixture (hereinafter referred to as mixture A), and stirs it until the whole is thoroughly mixed. By this addition the boiling will be interrupted, and, therefore, the whole mixture must be brought again into a boiling state. After this there is added 7 parts in weight of fine well sifted and thoroughly dried sawdust or pulverized bark, and the boiling is continued until the wood is thoroughly saturated, and becomes part of the mixture. The mixture A above referred to consists of 2 parts in weight of finely pulverized coal, and from 3 to 4 parts of bicarbonate of soda, or nitrate of lead or saltpetre, or their chemical equivalents. The requisite evaporation or drying of the mixture may be effected by means of open pans to which steam is applied, and the granulating process is the same as usual. *Patent completed.*

950. H. EATON. *Improvements appicable to presses for baling purposes.* Dated April 15, 1863.

We cannot here give space for the details of this invention. *Patent completed.*

951. J. S. MORTON. *Improvements in locks.* Dated April 15, 1863.

In these locks the key does not act directly upon the bolt, but upon a plate which the key causes to revolve. This plate is fitted inside the keyhole, and is kept in position to receive the key by means of a projection formed with a recess in which a pin on the revolving plate rests. The projection is formed on a curved bar, one end of which is free to move on a pin or stud, while the curved end rests in a segmental recess formed in one arm of a bell crank lever; the other arm of this lever is bent, and the end abuts against a tappet fixed on a rod held in the sides of the lock plate. This rod carries another tappet, at right angles, or nearly so, to that first-named, and is pressed against by a spring which rests upon the lock plate. The revolving plate carries a projecting arm, and, on the key being turned, it carries the plate with it, and the arm entering a notch in the bolt, and the motion of the key being continued, shoots the bolt. The key, in carrying the plate round comes in contact with the segmental recess in the bell crank lever, forces it back, and causes the tail to press upon one of the tappets on the rod before named; the pressing in of this tappet depresses the other tappet, and forces down the spring, and this tappet pressing at the same time upon one arm of a lever, raises the opposite arm, which is hooked, free from a locking lever, and the motion of the key being continued brings the arm on the circular plate into a notch on the tail of the locking lever, whereby the face of this lever, formed with a crutch, is forced behind and into a recess made in the bolt, and holds it secure until the motion of the key in the reverse direction, acting through the arm on the revolving plate, the bell crank lever, the tappet rod, and hooked lever, releases the locking lever; whereupon the hooked lever engages into the locking lever, releases the crutch from the bolt, and allows of the bolt being drawn back by the arm on the revolving plate entering the notch in the bolt. The working parts of the lock are at such a distance from the keyhole, that they are inaccessible, or nearly so, to any instrument for picking the lock. *Patent abandoned.*

952. A. V. NEWTON. *An improved construction of blowing apparatus.* (A communication.) Dated April 15, 1863.

According to this invention, a novel form of centrifugal blower is constructed, capable of being used singly or in combinations of two, three, or more blowers, the same being mounted one behind the other in the same case, but in separate chambers, which communicate the one with the other by central openings in the partitions which divide the case into the chambers. *Patent completed.*

953. T. B. E. FLETCHER. *Improvements in apparatus for collecting the solid portions of sewage.* Dated April 15, 1863.

Here a receptacle or pan is placed in any position where it will intercept the passage of the sewage from its source to the outlet; this receptacle is furnished at or near the top with two bends, one for the ingress of the sewage, and the other for the egress of the fluid portion only, the latter being provided with a grating to prevent solids from being washed through. *Patent completed.*

954. J. B. WATTS. *An improvement in steel sword hilts.* Dated April 16, 1863.

This consists in forming the "oval centre" for steel sword hilts of a separate piece, and of any suitable metal, at the same time removing that portion of the metal of the hilt where the oval centre requires to be situated, and then fixing the separate piece of metal in such place in the sword hilt either by soldering, rivetting, or otherwise. *Patent abandoned.*

955. J. L. McLAY. *Improvements applicable to mariners' compasses.* Dated April 16, 1863.

The object of this invention is to render the mariners' compass independent of local attraction generally when placed on board an iron ship, and consists in surrounding the compass with a ring or zone of brass, to which is attached a number of curved magnets placed at equal distances from each other, with their poles pointing outwards. The needle is placed so as to be in the plane of the centre of the length or breadth of the curved magnets which move with the compass bowl. *Patent abandoned.*

956. J. BAGGS and W. SIMPSON. *Improvements in purifying and treating coal gas, sulphuretted hydrogen, and other gases containing sulphuretted hydrogen, and in obtaining sulphur, sulphuric and other acids, in such treatment.* Dated April 16, 1863.

The main objects of this invention are twofold—firstly, the depriving of coal gas of elements which render it injurious to the animal and vegetable kingdom; and secondly, the manufacture of useful products from or with the elements of which the coal gas has been deprived. The patentees cause the gas to come in contact with metallic compounds, by blowing or otherwise, whereby the injurious adulterative matters are separated by decomposition or appropriation. The metallic compounds employed are mainly metallic oxides and salts, whether neutral salts, super-salts, or sub-salts, having a strong affinity or attraction for sulphur, carbonic acid, and other impurities; and which are themselves susceptible of renovation or recovery. The oxides and salts of copper, lead, magnesia, and other bases may be used for these purposes. *Patent completed.*

957. C. TERRETT. *Improvements in preventing incrustation in steam boilers.* Dated April 16, 1863.

This invention relates to a composition for preventing incrustation in steam boilers, and consists in a combination of terra japonica (Gambier), or Mimosa japonica, divi divi, cutch (catechu), and myrabolams. *Patent completed.*

PROVISIONAL PROTECTIONS.

Dated June 30, 1863.

1625. J. G. Jennings, Palace-road, Lambeth, sanitary engineer, and M. L. J. Lavater, Bath-street, Newgate-street, india rubber manufacturer. Improvements in stoppers and lids or covers for jars, bottles, and other vessels, also in closing and fastening other articles.

Dated July 3, 1863.

1653. H. Broadhead, captain R.N., and G. Murdoch, inspector of machinery in the Royal Navy, Portsmouth. Improvements in breech-loading ordnance, and gun carriages.

Dated August 12, 1863.

1993. R. Wappenstein, Manchester, engraver. A new method of preventing forgery of bankers' cheques and other documents by the use of a stamp, and a new apparatus whereby the issue of a stamped document is controlled.

Dated August 31, 1863.

2151. A. V. Newton, 66, Chancery-lane, mechanical draughtsman. Improvements in the mode of, and apparatus to be used in, sewing by machinery. (A communication.)

Dated September 3, 1863.

2177. N. Bailly, Vesoul, France, agent. Improvements in the application of rolling friction to the axle-boxes and journals of running shafts and axletrees of machines and vehicles of all descriptions for lessening the resistance to the motion. (Partly a communication.)

Dated September 24, 1863.

2359. A. V. Newton, 66, Chancery-lane, mechanical draughtsman. Improvements in the manufacture of gunpowder and powder for blasting purposes. (A communication.)

Dated September 28, 1863.

2376. T. Lowe, Brighton. An improved break for railway and other carriages.

Dated October 15, 1863.

2524. R. Bewley, jun., Uttoxeter, ironfounder. Improvements in wrenches.

2528. H. W. Hart, Fleet-street, engineer. Improvements in apparatus for suspending T and other like fastenings and articles to which they are applied.

Dated October 17, 1863.

2538. S. Berrisford, Stockport, engineer and machinist, and W. Ainsworth, overlooker. Certain improvements in looms for weaving.

Dated October 19, 1863.

2555. A. Budenberg, Manchester. An improved blasting powder. (A communication.)

Dated October 20, 1863.

2576. W. N. Hutchinson, Plymouth, major-general. Improvements in ordnance.

Dated October 21, 1863.

2579. T. C. Clarkson, 56, Stamford-street, Blackfriars, manufacturer. Improvements in the manufacture of saddles and harness, and in materials for, and in ornamenting the same, which improvements are applicable for parts of carriages, dress, and coverings for the head, and other articles.

2586. E. Alcan, King-street, City, merchant. An improved method of figuring and ornamenting cloths and other fabrics and apparatus employed therein. (A communication.)

Dated October 22, 1863.

2598. J. W. Friend, Freemantle, Southampton, and B. F. Weatherdon, Kingston-on-Thames, civil engineer. An improved valve and valve gear for regulating the passage or flow of fluids.

2602. J. Weems, Johnstone, Renfrew, engineer. Improvements in machinery, apparatus, or means for drying, cleaning, and cooling grain and other vegetable products.

2603. A. Kinder, 20, Cannon-street, engineer, and J. Inglis, Ellesmere-road, Old Ford, engineer. Improvements in the manufacture of metallic foils, and in the apparatus to be employed therein.

2604. B. Noakes and F. J. Wood, Bermondsey, iron cask manufacturers. Improvements in the manufacture of metallic casks, bottles, and other similar vessels, and in machinery employed therein.

Dated October 23, 1863.

2611. J. L. Jürgens, 4, Noel-street, Islington, navigator. Improvements in vessels of war.

2614. A. J. Martin, 2, Vernon-terrace, Roman-road, North Bow, chemist. An improved burner for burning petroleum, paraffin, or other hydrocarbon oils, consuming the smoke without the use of a draught chimney.

2619. F. Tolhausen, 17, Faubourg Montmartre, Paris. An improved mechanism for regulating the working of springs. (A communication.)

Dated October 24, 1863.

2630. W. Locke and J. Warrington, Kippax, near Leeds, coal owners, W. E. Carret, W. E. Marshall, and J. Telford, Leeds, engineers. Improvements in the working and mining of coal, minerals, and earthy matters, and in the machinery, apparatus, and means to be employed therein.

2634. B. Browne, 49, King William-street, City, civil engineer. Improvements in sewing machines. (A communication.)

Dated October 26, 1863.

2636. R. Littleboy, 2, John's-terrace, St. Leonard's-road, Bromley. Improvements in the manufacture of nosebags.

2638. F. Parker, Cambridge, carriage builder. Improvements in carriages.

2640. S. J. Healey, Manchester, engineer. Improvements in water gauges applicable to steam boilers and other purposes.

2642. J. Nicholas, Newton, oil refiner. Improvements in treating Canadian petroleum and other mineral oils of a similar nature.

2646. A. Blake, Newport, Monmouthshire, brewer. An improved refrigerator for cooling worts for brewing, or other liquids requiring cooling, and for improving brewers' refrigerators now in use.

Dated October 27, 1863.

2648. J. Marshall, 126, Pentonville-road, civil and mechanical engineer. Certain improvements in the expression of oil from oil-yielding substances, and in the production of oil cake and other residuary matters.

2654. J. Hutchinson and J. Hollingworth, Dobcross Saddleworth, machine makers. Improvements in means or apparatus employed in weaving.

2656. R. Smith, 24, Higher Chatham-street, Manchester, machinist. Improvements in doubling and winding machines.

2658. M. W. Carr, Knoll, Blackheath, civil engineer. Improvements in the manufacture of wooden sleepers for railways.

Dated October 28, 1863.

2660. W. Wanklyn, Albion Mills, Bury, cotton spinner. Improvements in apparatus for opening and conditioning cotton and other fibrous substances.

2662. A. S. Coronel, 256, High Holborn. An improved preparation of tobacco for fumigating purposes.

2664. S. Procter, Elsecar, mechanic. An improved instrument for extracting corks from bottles.

2665. E. Oldfield, Adelphi Iron Works, Salford, machine makers. Improvements in self-acting mules for spinning and doubling cotton and other fibrous materials.

2666. H. A. Bonneville, 24, Rue du Mont Thabor, Paris. An improvement in clasps for portemonnaies, pocket-books, bags, and other like uses. (A communication.)

2668. J. and J. Cavanah, 21, Parron-street, Paddington, Liverpool. Improvements in machinery or apparatus for

making bricks and tiles, applicable also for washing and drying clay.

2670. W. Nall, 1, Wharf-street, Leicester. Improvements in ornamenting glass and sheet gelatine.

2671. G. E. Donisthorpe, Leeds. Improvements in apparatus used when getting coal and other minerals.

2672. R. B. Jones, Limerick, gentleman. Improvements in portable cooking apparatus.

2673. J. Kennedy, Whitehaven, shipbuilder. Improvements in the construction of ships of war and other vessels and in masting and rigging the same.

2674. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in instruments for taking astronomical and other observations. (A communication.)

Dated October 29, 1863.

2676. O. C. Evans, Manchester. Improvements in digging machinery.

2677. J. R. Johnson, 31, Red Lion-square. Improvements in the manufacture of lubricating compounds.

2678. J. Rawlings, Carlton-hill East, gentleman. Improved means of attaching cords to window sashes.

Dated October 30, 1863.

2679. A. R. L. M. Normandy, Odin-lodge, King's-road, Clapham-park. Improvements in the manufacture of playing cards.

2680. F. N. Gisborne, 3, Adelaide-place, London-bridge, engineer and electrician. An improved composition for coating ships' bottoms.

2681. J. Nash, 37, Princes-street, Leicester-square, furniture dealer. An improved mattress for beds.

2683. H. Cochrane, Ormesby Iron Works, Middlesborough-on-Tees, Yorkshire, engineer. Improvements in surface condensers, also applicable to the refrigeration or cooling of fluids.

2684. W. M. Neilson, Glasgow, engineer. Improvements in taps, cocks, or valves. (A communication.)

2685. W. Gadd, Nottingham, lace manufacturer. Improvements in machinery or apparatus for the manufacture of bonnet and cap fronts, which improvements are also applicable to the production of ornamental effects to other trimmings for wearing apparel.

2687. M. J. Roberts, Pendarren-house, Crickhowell, esq. Improvements in apparatus for oiling wool.

2688. G. Rosselet, Rue Sainte Appoline, Paris. Improvements in apparatus for sustaining and raising ships or vessels, applicable also as life-buoys.

2689. A. Turner, Leicester, elastic web manufacturer, and W. E. Newton, Chancery-lane, civil engineer. Improvements in looms for weaving terry and cut pile fabrics, parts of which improvements are also applicable to other kinds of looms.

2691. A. Turner, Leicester, elastic web manufacturer. Improvements in looms for weaving.

2692. W. Verran, Penryn, Cornwall, mechanical engineer. Improvements in machinery for obtaining motive power by means of steam.

2693. H. Clow, Bland-street, Dover-road. Improvements in ovens.

2694. G. F. Busbridge, East Malling Mills, Kent. Improvements in apparatus for feeding sheets of sized or unsized paper to a drying machine.

2695. J. Brigham and R. Bickerton, Berwick-on-Tweed, implement makers. Improvements in reaping and mowing machines.

2696. J. H. Johnson, 47, Lincoln's-inn-fields, gentleman. Improvements in the manufacture of soap. (A communication.)

Dated October 31, 1863.

2701. J. Rennie, Birmingham, manufacturer. Improvements in the manufacture chandeliers, lamps, and other apparatus employed in distributing light.

2703. J. Getty, Temple-street, Liverpool. Improvements in building ships and vessels.

2705. W. Pope, Bristol, engineer and millwright. Improvements in machinery for breaking or crushing stone.

Dated November 2, 1863.

2711. W. E. Newton, 66, Chancery-lane, civil engineer. Improvements in clock-work movements. (A communication.)

Dated November 3, 1863.

2717. R. Eaton, Stockport, machinist. Improvements in machinery for ruling or marking leather.

2719. J. P. Booth, Cork, feather purifier. Improvements in beds and bedding.

Dated November 4, 1863.

2723. P. A. Sautreuil, Fécamp, France. An improved apparatus for the lubrication of bearings, shafts, or other parts of machinery subject to friction.

2725. J. Thomas, Battersea, ironfounder. Improvements in preparing ores and earths containing copper for smelting.

2731. J. A. Barral, officer of L. d'Hr., chemist, and L. A. Cochery, land owner, 10, Rue de la Fidelité, Paris. Certain improvements in the manufacture of manure.

PATENTS APPLIED FOR WITH COMPLETE SPECIFICATIONS.

Dated November 4, 1863.

2728. J. Tangye, Birmingham, manufacturer. Improvements in portable hydraulic shearing and rivetting machines.

Dated November 7, 1863.

2768. J. K. Hoyt, New York, United States. Improvements in revolving firearms. (A communication.)

2779. G. Haseltine, 12, Southampton-buildings, Chancery-lane, civil engineer. An improved machine for bending metallic pipes or spouts. (A communication.)

NOTICES OF INTENTION TO PROCEED WITH PATENTS.

From the *London Gazette*, November 17, 1863.

[illegible]. J. G. Jennings and M. L. J. Lavater. Stoppers.

16[illegible]. H. Broadhead and G. Murdoch. Breech-loading ordnance.

1665. J. Gimson. Shuttles.

1676. J. M. Croft. Propellers.

THE
MECHANICS' MAGAZINE.

LONDON, FRIDAY, NOVEMBER 27, 1863.

AUSTRALIAN TELEGRAPHY.

WE have just received a copy of the report on the progress and general condition of Electric Telegraphy in New South Wales, prepared by Mr. E. C. Cracknell, and laid before both Houses of the Australian Parliament during the recent session. Mr. Cracknell, as telegraph superintendent, is placed in a position to afford the fullest possible information, and he certainly has not been chary of communicating it. Although the report contains much that can only excite a local attention, it contains much to interest English readers as well; the funds necessary for the formation of the various lines which connect colony with colony, town with town, having been in many instances supplied by capitalists who have never ventured into the regions of the New World. It is satisfactory to learn that, as a commercial speculation, the extension of the telegraph system throughout New South Wales has been for the most part thoroughly successful; the lines in general being fully employed at remunerative charges. Very many extensions are proposed, and not a few in progress, the contract prices varying from £48 to £43 per mile. The length of the lines at work in the colony, at the date of the report, in April last, was 2,174 miles, the number of miles of wire being 2,539. When we consider that it is only five years since telegraphic communication was commenced in New South Wales, it must be admitted that the spirit of enterprise has not been absent in this important matter; while the profits show that the facilities for communication, placed at their disposal by the telegraph, have been fully appreciated by the public. The report, indeed, informs us that although "in the year 1858 this colony was far behind the sister colonies of Victoria and South Australia in the length of its lines, it can now boast of not only a greater number of miles of wire, but that it is the only Australian colony in which the electric telegraph returns a fair per-centage on the capital invested. The receipts, it seems, at nearly all the stations, show a steady increase, which is most encouraging, and augurs well for further progress. The public appear to evince increased confidence in this simple and expeditious means of communication; and when the works, which are now in progress, are completed, delays of a serious nature will seldom occur, and a still further increase in the revenue of the department may be expected."

The total capital invested amounts in round numbers to about £116,500—no inconsiderable sum for a thinly-peopled country like New South Wales. The net profit on this sum is stated to be £8,733, or, as nearly as possible, 7½ per cent. per annum. This is doubtless a very good result; but still better things may be looked for. Many of the intermediate stations, which are necessary for the maintenance of the through line, return little or no revenue as yet, while the formation of some of the branch lines has been too recent to permit much profit from them for the present.

As to the details involved in the daily working of the lines, Mr. Cracknell speaks boldly, and suggests improvements and alterations in an independent spirit which we admire. Many of our electricians will be surprised to learn that the Wheatstone's instruments, supplied from England in 1861, have not answered the purposes intended. They are apparently too complicated and delicate in their construction to be used by inexperienced operators, and cannot be made to work satisfactorily when a number of stations are connected in one circuit. They answer well enough, however, for short lines with only two terminal stations, and the report recommends, therefore, that their use be in future confined to short private lines, or branches from main lines to places which will not pay for a specially-trained operator. All the lines have worked well, and the expenditure for repairs has been trifling. The first section of the Northern Line, which is carried through a rugged and badly-timbered country, has given most trouble. The submarine cable at a place called Wiseman's Ferry, on the river Hawkesbury, has also been a source of great annoyance, the continuance of which has now been provided against by the substitution of masts and overhead wires. The mode of insulating all but the early lines has been very much improved; highly-glazed porcelain insulators, double umbrella, being now used, in place of the rough salt-glazed stoneware insulators. It is stated that the superiority of the former is rendered very manifest by the comparative ease and rapidity with which the lines so insulated can be worked in wet weather. For all future lines, and for repairs to those already constructed, much longer and larger poles will be used, the first cost of which will, perhaps, a little exceed those now erected, but they will eventually prove more economical, as the same poles, if 28 ft. long, when decayed near the surface of the ground, can be re-set, and will still be of sufficient length to admit of ordinary traffic passing under the wires. As an experiment, a number of wrought-iron posts have been imported; they consist of a galvanized wrought-iron tube, 15 ft. long, tapering towards the top, in which is fitted a 6-ft. wooden top carrying the cross-arms and insulators, the whole fitted into a cast-iron base 4½ ft. long, with cross-feet to keep the post in a perpendicular position; these are very light in appearance, and should be very durable; but their expense must be too great, we fear, to permit of their meeting with anything like extended adoption, even on the railway lines, as proposed in the report.

Perhaps the most important, certainly the most interesting, portion of Mr. Cracknell's Paper is a kind of appendix, embodying a proposal laid by that gentleman before the Secretary for Public Works, for the extension of the line of electric telegraph to Northern Australia, and its ultimate connection with the Dutch settlements, India, and Europe. Telegraphic communication at present exists, and is in daily operation, between London and Bagdad, and from Kurrachee to Rangoon, in the Bay of Bengal. The gaps to be filled up are from Bagdad to Kurrachee, a distance of 1,410 miles, arrangements for which have been entered into; and the contract for the Persian Gulf cable has been given long since, as our readers are aware, to Mr. Henley, to be ready and laid by the end of the present year. The next length to be provided for is from Rangoon to Singapore, a distance of 1,090 nautical miles. This section the Indian Government have consented either to subsidize or assist in carrying out coincidently with the other extensions. The Dutch Government have entered into arrangements with Mr. Gisborne for the supply and submersion of a new cable, on the most approved principle, between Singapore and Batavia, which, in connection with their existing land lines, will in less than two years establish communication to the east end of Java. The next link is the Australian section, which Mr. Gisborne proposes should terminate either at Brisbane or Broad Sound; but now that the northern colony, Queensland, is daily becoming more settled, a land line would be perhaps more suitable. Mr. Cracknell proposes the following as the best route:—

The Queensland Government to extend their existing lines to Rockhampton, and from thence to, say, Peak Downs or some other point to be determined on, within the settled districts, to be then continued jointly between the colonies of New South Wales and Queensland, to, say, 138 deg. east; from thence to Van Diemen's Gulf, to be constructed by the South Australian Government, or, in the event of that Government not approving of this proposal, the line should terminate at the Albert River, Gulf of Carpentaria (which would reduce the land line, to be constructed by the two colonies, to 700 miles), and there join the submarine cable, which would touch at Port Essington, and continue to Coepang and Cape Sedano, East Java; the distances being as follows:—

From Albert River to Port Essington	660	knots.
From Port Essington to Coepang	525	„
From Coepang to Cape Sedano	590	„

According to another scheme proposed by Mr. Todd, the line would be carried overland direct from Adelaide across the continent to Van Diemen's Gulf, an estimated distance of 2,000 miles. The proposal would doubtless have been more feasible were the country settled; as it is, there are no intermediate places of sufficient importance to assist the receipts. Mr. Cracknell has, therefore, apparently good grounds for preferring the line which he proposes himself. For the construction of the land line he recommends an entire change from the present system:—"Thus—instead of thirty posts, 23 ft. in length, to the mile, I would place only ten posts, 40 ft. high, with a light steel wire conductor of the same size as the *over-house* wires now used by private firms in London, No. 11 wire gauge. I would also substitute a bell-shaped ebonite insulator instead of the more expensive and fragile articles now in use, and a zinc rain shield round the post, about a foot from the top. By this means a dry zone can always be insured, and the highest points of insulation attained."

The advantages to be derived from telegraphic communication with our Australian colonies can scarcely be over-estimated. The total through charge, for a twenty-word message, from London to Melbourne, *via* Asia Minor, would not exceed £6. The expenses of constructing the line through its various portions would not be very heavy, and might be ultimately defrayed by a joint Government subsidy, extending over a period of, say, thirty years. Mr. Gisborne proposes to convey free messages for the several Governments to the extent of the subsidy. This liberal offer reduces the whole matter, as far as the Australian colonies are concerned, to the construction and working of 700 miles of land line, the former of which (at a cost of £70,000, bearing an interest of 5 per cent.) would form an annual charge of £3,500, and with the working expenses, which are estimated at £9,800 per annum, would be provided by the two colonies; against these would be placed the profits derived from the undertaking. Mr. Cracknell considers the submarine cable, proposed by Mr. Gisborne, to be one well adapted for the route intended; it has a much larger conductor than the original sample; it is much heavier, and is provided with an outer coating of equal parts of jute, bitumen, and hydraulic mortar, which will prevent the corrosion of the protecting wires, and admit of the cable being lifted for repairs without fear of fracture. The shallow soundings, throughout the entire distance, are also

much in favour of the successful laying and working of the cable—a depth of more than fifty fathoms being seldom attained; the distances are also very convenient, being only 660 knots for the longest length—that between Albert River and Port Essington—which will admit a speed of not less than from twenty to twenty-five words a minute.

THE "BELLEROPHON" TARGET.

A PARAGRAPH describing the armour proposed to be applied to Mr. Reed's iron frigate "Bellerophon," which has more than once gone the round of the press, propounds the plan as something new, and as Mr. Reed's invention. In this statement there is a double error, affecting the novelty and design of the system, which is to be tested in the target constructed by the Millwall Company, and now being erected at Shoeburyness for trial, under the supervision of Mr. Baskcomb, the Admiralty Inspector.

Shortly after the conclusion of the armour plate experiments during the past summer, the Chief Constructor and Mr. Baskcomb paid a visit to the practising-ground at Shoeburyness, where they inspected the dismantled targets, and examined carefully their construction, as well as the effects of the projectiles, which had been fired at them. One of the targets consisted of three plates, supplied by Messrs. Brown and Co., of Sheffield, fastened to an iron frame and teak backing, forming a structure which is the type of the proposed "Bellerophon" armour. The two Admiralty officials conceiving that this combination of iron and wood exhibited greater powers of resistance than any other, Mr. Reed determined to adopt the plan.

Our naval, military, and scientific readers will remember the trial of the Armstrong and Whitworth shells, and the heavy 150 and 300 pounder solid shot, which took place at Shoeburyness the 17th March last, and which was reported in the MECHANICS' MAGAZINE a few days after. It was the target referred to at which those missiles were fired.

The three plates differed in thickness—one being 5½, one 6¼, one 7¼ in. Half the length of the plates was left hollow, the other half was backed with teak 9 in. thick, supported behind by iron skin plates 2 in. thick, fastened to iron frames of about the same dimensions and the same distance apart as those proposed for the "Bellerophon." Taking 5½-in. armour plates, increasing the wood-backing to 12 in. (variously stated 10 to 12 in.), we have the combination, of which the invention is ascribed to Mr. Reed, but which really was the result of the accidental circumstance, that the three plates in question, were fastened to the frame of the Samuda target, of which the skin plates were 2 in. thick.

From the result of the experiments on the Brown-Samuda structure, we may form a pretty correct notion what will be the power of resistance of the "Bellerophon" target. Whatever it may be, in comparing it with other systems, we must look to the respective weights of the materials. The weight of the "Warrior" target, consisting of 4½-in. armour plates, 18 in. of teak backing, and ¾ in. skin plates, was 346 lbs. per superficial foot; that of the "Bellerophon," having 5½-in. armour plate, 12 in. of teak, and 2-in. skin plates, will be about 400 lbs., or nearly 60 lbs. per foot more. This is a great addition to the strength of the armour; it is, of course, calculated to offer greater resistance than the "Warrior" section; and before the "Bellerophon" armour can be fairly contrasted wit any of the systems which have been experimented upon, or may be proposed, the latter ought to be tested by giving them the same weight of materials. In all trials in competition with the "Warrior" plan, the weight was limited by the authorities to 346 lbs. per foot. It is to be expected that, with 60 lbs. per foot more, the resistance of the mass will be greater; but as regards the armour plates themselves and the backing, irrespective of the skin plates, we have as a guide the experiments tried at Shoeburyness on the "Minotaur" target, of which the armour plates were 5½ in., and the teak backing 9 in. thick. The result was anything but encouraging; for the plates, although 5½ in. thick, were more damaged and more extensively buckled than the the 4½ in. "Warrior" plates. So unsatisfactory at the time was this trial considered, that the Admiralty proposed to the contractors for the "Minotaur," "Northumberland," and "Agincourt" two new plans of armour for those vessels, and asked for estimates of the expense. An increase of some £8,000 or £10,000 on each ship being demanded, the Admiralty abandoned the new plans, which, of course, were thought to be an improvement, otherwise they would not have been proposed. The three ships were ordered to be armour-plated in accordance with the original design, which, as we have stated, on being tried in the form of the "Minotaur" target had proved to be a failure. Thus is the defence of England on the seas trifled with and imperilled.

Whilst millions are squandered in constructing experimental ships and guns without previous trial, in an ill-considered spirit of economy, a system of protecting ships proved by experiment to be defective is adopted in preference to a more effective one. Of what use are our costly gunnery experiments if the teaching they afford is disregarded?

STEAM TO AMERICA.

IF the number of new joint-stock companies which daily start into existence can be taken as evidence, this grand old country of ours is suffering just now from a plethora of wealth—a superabundance of capital, in fact, for which it is difficult to find an investment. It is far from likely that all the gentlemen who set schemes on foot, are possessed of the Midas-like faculty of turning that which they touch into gold. Yet, among the many projects, some of them wild enough in all conscience, now before the public, we find at least a few distinguished by a sound mercantile appreciation of all those points necessary to pecuniary success. Mines, banks, railways, hotels, come in for a fair share of patronage, and, perhaps, a little of the latest, the establishment of new steamship lines begins to attract the attention of those who wish to expend their money to advantage. Seven-and-twenty years ago the project for establishing a line of steamships between this country and America, was first announced to the world. The "Savannah," and the "Curaçoa," had already performed the voyage, and thereby demonstrated the practicability of the enterprise, in a nautical and mechanical sense. As to the commercial aspect of the question, direct evidence was wanting. The scheme was a new thing in the world, the like of which had never gone before; and in consequence the possession of experience was out of the question. Many were the debates, turbulent the discussions, which followed on the proposal. At length, eight steamships were placed on the line, and for some time kept up the communication between the countries, with a doubtful kind of success as far as the passages were concerned, and with a certain and ruinous loss to their owners. It soon became evident, in short, that such a line could not possibly succeed under then existing arrangements, without the aid of a Government subvention. The Cunard line then started into existence. Every circumstance connected with it is too well-known to require comment; but we may remark that the failure of the first scheme for Transatlantic communication by the aid of steam, was sufficient to prevent for many years, the setting on foot of any other which proposed to rest entirely on its own resources.

Granting that an ocean steamship finds full employment, the profit to be derived from her voyages in the regular course of trade, will depend mainly on her working expenses, and her available carrying capacity. A large proportion of the former are absorbed in the purchase of fuel and the repairs of the machinery. The latter is determined with a given tonnage, by the quantity of coal which it is necessary to take on board at one time; what this may be, depending again on the length of the voyage, the speed maintained, and the good or bad qualities of the engines. What is true of one vessel thus far, may be applied to an entire fleet; and it follows that, in the present day, thanks to the improvements which the steam-engine has received, the necessity for a Government subsidy depends almost wholly on the observance of certain conditions as to speed, with the neglect of which the want of pecuniary aid at once disappears. Such was not the case, however, in the infancy of steam navigation. The maximum speed attained seldom exceeded that of clipper sailing ships. In the steady maintenance of a certain velocity, notwithstanding adverse gales and boisterous seas, resided the only superiority of steam over wind as a means of propulsion; and this power could only be obtained by the use of ponderous machinery, and full cargoes of coal which absorbed all the tonnage which should have been available for merchandise. The profitable load carried was of course reduced to a minimum, and thus the subsidy became absolutely essential to the maintenance of the mail service. The result of every improvement in steam machinery has been hitherto except in exceptional cases, an increase in the speed maintained, and seldom or never a reduction in the quantity of fuel carried. The policy of this system may be questioned but not overturned, so long as it is confined to the postal service. Mails cannot be conveyed at too high a speed; and the revenues of the Post-office are ample enough to meet even greater demands than those made on them now. But when we consider the questions involved in the conveyance of goods and passengers alone, we find that great speed is no longer a thing of paramount importance; and it becomes a simple matter of calculation to determine exactly how much it must be reduced to enable a steamship line to dispense with the aid derived from a Government subsidy.

A project for the formation of a new Translantic Steamship Company has recently been brought before the commercial world. The Inman line appears to pay its way pretty well without external aid, although the engines employed are not remarkable for economy, and a very fair speed is maintained. Finding a *point d'appui* in the deductions which may be drawn from this fact, the projectors of the new line propose to construct ships of that size which experience has demonstrated to be best adapted to the requirements of the service which they will undertake, fitted with engines combining the most recent improvements under the most compact form. As the attainment of an excessive speed is deemed un-

necessary, the consumption of fuel will be extremely moderate; and little doubt is entertained that the ships will, in consequence, prove highly remunerative to their owners, without the aid of any subsidy whatever. It is out of our province to consider the prospects which such a line enjoys of full cargoes and plenty of passengers; but granting that these can be procured, either by a slight reduction on existing tariffs, or by providing increased accommodation, there is no reason why the scheme should not be successful. The mail steamers, as recent events have proved, keep time, at a considerable risk; their velocity being maintained now and then with an enterprise which merges into rashness. The danger encountered from fog or iceberg is seldom regarded as of much importance when compared with advantages to be derived from the saving of a few hours in the time required for the passage. We presume that all this is taken into account by the underwriters. The machinery, too, of these boats is taxed to the utmost limit of safety, and their coal bills are of course very heavy. A given weight of engine will produce more power when the steam follows the piston with a full pressure throughout the stroke, than it will when expansion is largely employed. Speed is paid for by the Government, and speed must be got, no matter at what expense of fuel. Any economical expedient which would reduce the gross power of the engines, is therefore regarded as totally inadmissible in conducting the postal service; but the case is far different with vessels not bound to time. The uninitiated have little idea of the saving in fuel which is effected by a very trifling reduction of speed—a saving, indeed, very much greater than anything which mere mechanical improvements in the construction of the engines can possibly effect. If we take the case of a great ocean steamer, of the "Scotia" or "Persia" class, for example, we will find that the hourly consumption of fuel per indicated horse-power is not much, if anything, under 4 lbs. The distance run per trip is probably 3,000 knots; and in order to accomplish this in nine days or thereabouts, a speed of 14 knots must be steadily maintained. This will require the exertion of probably 4,000-horse power, and a gross consumption of fuel equal to about 1,500 tons in the same time. This varies, however, as the square of the speed, if we disregard time and base our calculations on the performance of each separate voyage. Consequently, by simply reducing the speed to, say, 10 knots per hour, for the sake of illustration, and increasing the whole duration of the trip from 9 to 12·5 days, the consumption of fuel will be reduced in the proportion of 10^2 to 14^2, or as 100 is to 196. In other words, instead of 1,500 tons, about 765 will suffice for each voyage. The sea-going expenses of the ship—such as the coals and maintenance of the crew and passengers—will, of course, be in direct proportion to the number of days which she remains at sea, and therefore will be augmented in the ratio of the reduction in speed, an item probably far overbalanced by the reduction in the amount paid for coals, leaving the profits to be derived from the additional 700 tons of cargo space as clear gain to the owners.

There is, however, a limit to this reduction in speed which cannot safely be overstepped, and steam-engine economy, therefore, becomes a matter of vital importance to any company working a line of steamers depending wholly on its own resources for the settlement of the great question of profit and loss. In the calculation which we have just made, we have reckoned on a consumption of 4 lbs. per horse-power per hour of good coal; and with the side, lever engine, surface condensation, and its attendant evil "blowing off," it is not likely that it can ever be much less. Any saving in the weight of fuel carried, permits the use of a heavier engine. Machinery of sufficient size to propel the ship at the required speed, even when the principle of expansion is extended to the utmost rational limit, can then always be employed, and the economy of fuel advanced a step further by reducing the hourly consumption from 4 lbs. to 2·5 lbs. This is no visionary idea. Many of the Mediterranean steamboats, fitted with Maudslay's three-cylinder engines, get on very well with this allowance, and that with very simple machinery, involving nothing occult in its principles or management. Keen competition between companies who have no fatherly Government to assist them in their difficulties, quickly engenders a warm appreciation of the merits of coal-saving machinery; and it is not perhaps too much to say that the commercial success of many an enterprise of the kind under consideration, has resulted from the skill of the engineer on whom the construction of the engines has devolved.

As to the direct means of propulsion employed, we cannot think the adoption by an unsubsidized company of the paddle-wheel as very desirable. The engines absorb the most valuable cargo space by their position on board; and they are, for the most part, very heavy, from the great size rendered necessary by a slow piston speed. The screw is preferable in every way, as it permits of the use of sails to any required extent, and, in consequence, very fast passages may be performed, even with engines which class between auxiliary and those of full power. For the very highest speeds the paddle is at present preferred: how much longer it will enjoy this favour, it is not easy to say; but it should find no place in a fleet destined for moderate velocities.

Not the least sensible feature of the proposed undertaking, is that of providing for the carriage of sufficient coal to last the double voyage, out and home. Coaling at a foreign port is a serious item of expense. It is difficult to meet with any coal equal to that produced by our own mines; and the cost and risk of sending a cargo on a long sea-voyage to a distant port, there to be unloaded and loaded again, is by all means to be avoided. American coal is very inferior to ours as a rule; while recent events have raised its price to a degree never dreamt of by the wildest speculators. According to recent quotations, none could be procured at much under 11 dols. per ton, and it was expected to rise to 25 dols.! This pressure may be only temporary; but it is well to provide not only against the consequences of its continuance, but its recurrence. There is really nothing to prevent a steamship of a couple of thousand tons burden carrying fuel enough to last her some twenty days, provided that all the necessary arrangements are made beforehand; and we may rest assured that, in the capability of doing so, resides an element of commercial success which will amply compensate for a slight diminution in speed.

THE ORDNANCE REPORT, 1863, CONDENSED; AND CONCLUSIONS FROM IT.

No. III.

THE ELSWICK COMPANY AND ITS COMPETITORS.

BY an *àpropos* coincidence, on Friday last, the day our Condensed Report of the Ordnance Committee showed the preferential position of the Elswick Company over all competitors, an account was published, in the *Times*, of experiments at Shoeburyness with a 600-pounder 22-ton Armstrong gun on the shunting principle. It is not, at present, our purpose to make any comment on the performance of that cumbrous piece of ordnance, or to consider its value for the service. Time and further experiments will show, whether it will be more successful than the other products of its constructor; or, whether like them, when fully tested, it will, as regards efficiency for the military or naval service, prove to be practically a failure. This monster gun produced at the Elswick factory, and ordered and paid for by the Government, is an illustration and corroboration of the favour shown by the War-office to the Armstrong party, to the exclusion of other ordnance manufacturers.

The preference and favour are all the more reprehensible, because the principle called "the shunt"* has been tested by the Ordnance Select Committee in competition with other plans of rifling, and proved, by their own report, to be the most destructive to the gun out of twenty trials of different systems. In our last number we showed, from the evidence, that in the experiments referred to, the Armstrong shunt burst at the fourth round, and the Blakeley and Bashley Britten rifled gun stood 133 rounds. The experiments which gave these results were with cast-iron guns; but they were *comparative*, and in principle applicable to wrought-iron guns. In the face of the decisive superiority of the Bashley Britten rifling over the Armstrong, the Elswick Company received an order to make a 600-pounder shunt; and Captain Blakeley, who offered to make and lend to the Government a heavy wrought-iron gun for trial, at his own expense, met with a flat refusal. Who is answerable for this disregard of the teachings of costly experiments at the public expense—this persistent official patronage of one man and his co-partners, to the sacrifice of the national interest? This act of the Government, and the partial and exaggerated report in the *Times* of the alleged satisfactory nature of the experiments with the 600-powder shunt gun, seem to indicate a determination, on the part of the authorities, to maintain the Armstrong monopoly.

We proceed with the evidence from the Ordnance Report. Captain Blakeley says:—"If Sir W. Armstrong makes the gun with a steel barrel, enclosed in a casing of coils, he makes precisely that gun which I had the honour of offering to the British Government in 1855—minus the rifling. My object in 1855 was to obtain a very powerful gun. In 1855 it was not the object of the Government to obtain a rifled gun." (No 4,650 to 4,654.) "I laid my plan before the Government in 1854. Sir W. Armstrong's first gun was made in 1855." (No. 4,677.) "The competition, preparatory to the introduction of the Armstrong gun into the service, ought to have been more generally known. I was not aware, till last year, that there was a committee sitting on rifled ordnance," (No. 4,621.) "I am afraid my correspondence with the War Department will show that I thought myself very ill-used, and that I got rather out of temper." (No. 4,663.)

Captain Blakeley thus proves three things:—1st. In 1854 and 1855 he proposed to the War-office to strengthen guns on the plan

* The term "shunt" was meant by the inventor to convey the idea that the ribs of the projectile shunted from one set of grooves to another; but no such action takes place. The shot is a mechanical fit, the ribs shift from their driving to their bearing side like any other mechanical fitting rifling. The peculiarity of the plan consists in the bearing surfaces of the ribs being lined with studs or strips of soft metal, a plan which is copied from the Prussian projectile.

afterwards introduced by Sir W. Armstrong. 2. He received no encouragement from the Government. 3. He received no intimation from the War-office authorities, and did not know till they were over, that competitive trials of rifled ordnance were to take place. He next proves:—"The 10th October, 1860, I wrote to the Admiralty:—'I am willing to supply Her Majesty's Government with guns (to penetrate armour plates) either at its expense, payment being contingent on the gun performing what I promised, or else at my own expense entirely.'" Being referred from the Admiralty to the War-office, he wrote to that Department, and not only offered to "construct a 200-pounder, but lend it for trial. The reply was, that the gun could not be tested." (No. 4,760-61-62.) "I also offered to contract for the supply of cannon, at a less rate than that charged by the Elswick Ordnance Company, and I was refused." (No. 4,762 to 4,764.) "I asked leave to compete for the production of rifled guns with Sir W. Armstrong and Mr. Whitworth. I offered to conduct all the experiments at my own expense. My offer was refused." (No. 4,746.)

Mr. Whitworth was also deluded with the trial of his polygonal rifling in old service guns. In 1856 and 1858, he rifled seven brass and three cast-iron guns, supplied to him by the War-office. The former met with considerable success. The latter—two 32 and one 68-pounder—proved the efficacy of the rifling for destructive effect, but burst after a few rounds with heavy charges, owing to the weakness of the cast iron. As a witness, Mr. Whitworth says:—"In 1858, after the cast-iron guns, supplied to me by the Government, were proved to be too weak, I received an intimation that no more guns were to be rifled on the Whitworth principle." (No. 2,469.) "No other reason was given." (No. 2,471.) "The 68-pounder fired its projectile completely through the 4-inch plate and timber side of the 'Alfred' in 1858 at 460 yards." (No. 2,485-86.) "In 1858, flat-fronted shot, from a Whitworth 32-pounder gun, penetrated a ship's bottom through 40 ft. of water and 8 in. of oak, 3 ft. below the surface."

Sir William Armstrong's "shunt" rifling, as applied to cast-iron guns, was a complete failure; yet he received orders to a great extent to apply the shunt principle to wrought-iron guns. Mr. Whitworth could not obtain the same privilege. The unsuccessful trials of his rifling with cast-iron guns, was the only reason given for not testing it with wrought-iron guns. Injustice to Mr. Whitworth and partially to Sir W. Armstrong are here plainly manifested.

Mr. Whitworth, referring to the trial of his gun the end of 1858, complains (No. 3,058-59) —"I never was present at any intended trial of my own gun to show the accuracy and range and every particular." "My complaint is, that I was not present at the trials, which I understood were to take place between my gun and Sir William Armstrong's; that I did not know of any such trials; and my gun, I maintain, had not a sufficient number of trials to enable the Committee to come to any conclusion respecting it."

Captain Noble proved that the Whitworth gun was tried only eight or nine times, and the Armstrong forty-five or fifty times, in the experiments that determined the adoption of the system which has cost the country so dearly. Captain Noble contradicted Mr. Whitworth as to his presence at the experiments, maintaining that he always had notice to attend trials, and, in fact, was present three or four times; but, being pressed, Captain Noble admitted (No. 3,093 to 3,094)—"I speak only from recollection; I know as a fact, we did not make notes at the time, whether the inventor was present or not; I can't show by the records in the office whether Mr. Whitworth was invited or not." Here is a question of credibility of witnesses, which the public must decide, remembering that Captain Noble is the partizan and partner of Sir W. Armstrong.

Mr. Whitworth's correspondence, printed in the Appendix, shows that from the 14th October to the 22nd December, 1858, he was unable to attend the experiments at Shoeburyness which, nevertheless, proceeded in his absence; and Captain Noble proves (No. 3,109) that the fuses which were wanting to make a complete trial of Mr. Whitworth's gun "could have been elaborated at Woolwich, but the Committee could not have got them before the trials, *being required to report immediately upon the subject*." Mr. Whitworth also reminded the Committee, at the time of the trials in 1858, "that three years ago (1855) he bored and rifled guns for the Government, from which he expected valuable data, by their being submitted to a regular course of practice, which he hopes will now be done, for" (up to the time of his writing, 1858) "these guns remained unnoticed." This refers to the brass guns he rifled for the Government. They would have stood, as they afterwards did, a long continuance of heavy firing; but that chance was not given to him at the proper time. The cast-iron guns having burst from their innate weakness, his system was hastily condemned for that reason, and no other.

With reference to the supply of projectiles for Mr. Whitworth's gun, at the competition with Sir W. Armstrong, a suggestive fact is brought to light by a letter, dated 30th Oct., 1858, addressed to Mr. Whitworth, by order of General Peel, directing him "to suspend preparation of the shells and shot ordered the 1st Oct., as the Committee on Rifled Cannon have a sufficient supply, and it is not probable any more will be required." This was written at the time the trial was in progress. When it was over, Mr. Whitworth was told his gun could not be fired with shells, because he had not supplied any.

The spirit in which these experiments were made, with the view of precipitating a decision, is manifested in the following passage of the instructions to the Committee:—"Major-General Peel does not wish time to be lost in the pursuit of further improvements." The Committee having been appointed 8th Sept., 1858, notice of the intended experiments was given to Sir W. Armstrong the 15th, and he replies the 17th September, giving a list of "seven guns, which may shortly be delivered at Shoeburyness," showing his complete state of preparation for the coming trial.

Mr. Bashley Britten was too late to give evidence before the Parliamentary Committee. At the request of the Chairman, he addressed to him a letter, dated 8th July, 1863, in which he refers to letters written by him to the War-office between the 1st April, 1859, and the 27th July, 1860, urging the propriety of stronger guns (than cast iron) being tried on his plan, and adds:—"Even up to the present time I have had no opportunities of demonstrating the advantages of my system of rifled ordnance, on anything like equal terms with other inventors." He goes on to state that "the Ordnance Select Committee, on the 27th July, 1860, recommended the construction of a heavy brass gun for the trial of my system. For this gun I was desired to furnish drawings of the rifling; this I did at once, but the gun has never been made."

Mr. C. W. Lancaster, having received a letter from the "Committee on Rifled Cannon," inviting him to furnish them with his views on the subject of rifling ordnance, replied the 15th October, 1858:—"I have to regret that the tenor of the replies received, in answer to my letters to the War Department, at present prevents my self-devotion to the Committee; when existing impediments are removed, by a recognition of my just claims, I shall have a pleasure to furnish the best information I can communicate."

Under a strong impression of the treatment he had met with, Mr. Lancaster no doubt conceived that justice would not be done to him, and declined having anything to do with the proceedings of the Committee. He, like Captain Blakeley and Mr. Bashley Britten, had just cause of complaint, on the ground that, in the trial of his system with cast-iron guns, he stood second at the top of the list, and he received no order from Government to construct a wrought-iron gun on his principle; whereas, as we have seen, Sir William Armstrong, whose shunt rifling was the most defective of all the plans tried, nevertheless was authorized to make several shunt wrought-iron guns for the Government account.

Mr. Westley Richards, a well-known gunmaker, who has devoted a good deal of attention to rifled guns, was examined at great length. He altogether condemns the experiments made by the War-office, and considers they have not been fairly conducted. In his evidence, he says:—"The guns were not, as they ought to have been, identical in construction, weight, calibre, and length, or in the projectiles, and charges with which they were fired." (No. 3,968 to 3,998.) "The rifling principle was the question to be tried." (No. 3,979.) "Competitive trials between guns should be made in public; any one taking an interest in the matter should be allowed to witness experiments before a final decision is come to about any particular gun." (No. 3,991.) "I think when scientific men ask permission to witness experiments, they ought to be allowed to do so. I was anxious to see some large guns tried. There was a trial of Sir W. Armstrong's, Mr. Whitworth's, and Mr. Lynall Thomas's large guns, and I was refused permission to see those guns fired." (No. 3,994 and 3,995.)

Commander Scott, R.N., a distinguished and experienced officer, and a practical artillerist, who was deputed by Government to watch and report upon certain experiments at Shoeburyness, and is the inventor and patentee of a system of rifling which has been successfully adopted, under his license, by Captain Blakeley, expresses dissatisfaction at the treatment inventors receive at the hands of the Ordnance authorities. He says:—"I see no way in which there has been any opportunity given of testing whether there was a better gun or not than the Armstrong." (No. 4,117.)

"Do you object then to the system that has been pursued with respect to inventors by the Ordnance Select Committee?"

"Certainly." (No. 4,118.)

"Will you state your reasons?"

"The guns have not been tried under the same conditions, nor were the projectiles alike in windage and weight." (No. 4,119.)

Referring to the injudicious mode of proceeding of the War Department, Commander Scott says:—"The Committee (which approved of the adoption of the Armstrong naval guns into the service) was appointed by the War Department. Colonel St. George was president—the president of the present Committee;

Captain Wiseman was vice-president, he being vice-president of the present Committee. Sir W. Armstrong, himself, was a member, and also Captain Noble, who, immediately after the adoption of the gun as a field-piece, became his partner." (No. 4,196.) So that Colonel St. George and Captain Wiseman were members of the Committee which recommended, and of the Committee which approved on their own report, the adoption of the Armstrong guns. The direct personal interest which the other two members of the first Committee had in the matter, has been already pointed out.

The reply of the Duke of Somerset to question No. 5,145 appropriately closes the extracts relating to the general conduct towards inventors of the Ordnance Department :—" I do not think that inventors are very fond of the Ordnance Select Committee. They used to come to me, many of them, because they said they did not like the Ordnance Committee."

The foregoing extracts are not a tithe of the evidence proving the protection to Armstrong guns, no matter of what kind or class, and hostility to all other guns, systematically exercised by the War Department officials, from 1854 to 1863. The result, which might be anticipated, and probably was foreseen by Sir W. Armstrong and his supporters, naturally ensued. This result is proved by the evidence of Mr. T. G. Baring, Secretary for War in 1861: —" The Committee will see that at that time (when the heavy Armstrong ordnance was adopted into the service) there was no other gun before the War-office, which could be put at all in competition with the Armstrong gun; indeed, I may say there was no gun at all. *Therefore*, the Armstrong gun was the gun to be manufactured." That is to say, not because it was the best gun, but because no provision had been made by the War Department to test or produce any other gun. All other projectors and manufacturers but Sir W. Armstrong and the Elswick Company, were kept in ignorance of any competition, or withdrew from it in disgust. It was Hobson's choice. At a moment of peril, when war with America was imminent, the Admiralty was forced to accept the Armstrong 110-pounder, which has since been found totally unfit for broadside guns.

The facts proving gross partiality, are too patent to admit of doubt. As to the subordinate officers, and members of Committees, no censure can be cast upon them, for the zeal and efficiency with which they carried out the measures planned in the superior regions of the War-office. In the military *regime*, " to hear is to obey." They saw, plainly enough, that the Armstrong system was in favour in the highest quarters, and was destined to supersede all others. Under the circumstances detailed, competition was a farce. The Elswick Ordnance Company, no doubt planned in 1854, when Mr. Armstrong obtained his first order from the Duke of Newcastle, was looming in the distance. It was the prize sought after. By means, which, perhaps, the future may reveal, vast administrative and official patronage was brought to bear to further the grand scheme of the projector. Complete success in a pecuniary sense crowned his skilful combinations. The facts proved by the evidence exhibit, if not jobbery, official infatuation and favouritism. The same year, 1859, saw the Elswick Company an accomplished fact, all rivals set aside, and Mr. Armstrong, Sir William.

NEW PORTABLE STEAM PUMP.

M. LOUVIE, of Brussels, has invented a double-action pump of great simplicity, which, being at once self-acting and almost devoid of machinery, may prove useful in many situations where fuel is not expensive or facilities for repairs very accessible. It has no pistons, and is put in action by the alternate pressure and condensation of steam; drawing and discharging a continuous stream of water. The absence of mechanism points it out as being peculiarly adapted for feeding steam boilers.

It consists of two sheet-iron cylinders, and a third vessel resembling them, which, serving as a reservoir for compressed air, is surmounted by a tube through which the water is discharged—this tube descends within the air-vessel; secondly, of two suction tubes uniting into one, and two tubes connected with the air-vessel—all four being provided with clack valves; and thirdly, of a small pipe placed between the two first-mentioned cylinders, and communicating alternately with each, in order to condense the steam by a jet of cold water, which, passing from the full cylinder into that containing steam, instantaneously produces a vacuum, and causes the ascent of the water. Between the pump barrels is placed a small receiver, full of cold water, which serves to start the apparatus at first. This is evidently an improved model of Savary's engine, costing very little money, and, doubtless, capable of doing good service in many situations.

A NEW MONSTER RAILWAY BRIDGE.

AMONG the Parliamentary notices this season is one for the construction of a railway bridge across the Forth, to facilitate the communication between the Eastern Lowlands of Scotland and the North, the traffic at present passing either by the route of the Western Lowlands to the North, *i.e.*, *via* the Scottish Central Railway, to Stirling and Perth, or by a railway ferry at Burntisland, which is found expensive, cumbrous, and liable to detention. The point thought of to construct a bridge at first was Queensferry; but the Admiralty object to any structure which would prevent their ships passing to the anchorage above; while the depth of the water is also another reason why the only bridge permissible there should be a railway bridge. But the span of such a bridge would exceed anything hitherto known. Consequently, a point farther up the river had to be selected. The point which the Parliamentary notices state to have been fixed upon is a point about four miles above Queensferry, and is stated to be the point at which the Edinburgh and Glasgow Railway on the south side, and the Dunfermline Railways on the north side of the Frith, run nearest to the respective shores. Locally the point is known, on the south side, as Pardovan, and on the north side as Charleston. It is said that the depth of water, the nature of the soil in the river bed, and the character of the approaches on each side, are favourable to the construction of a bridge at this point of the river, and that a moderate headway only will be required.

This new bridge is proposed to be constructed by an independent company, who will afford running powers and facilities to all the railway companies choosing to make use of it. It is obvious that it must be used by the several lines running to the east coast from Edinburgh, and also, we should apprehend, by the Caledonian. These lines will all be able to reach the bridge by very short extensions.

This bridge, which will be built on about fifty piers, will necessarily be of great length—nearly as long, it is said, as the Victoria Bridge across the St. Lawrence. It will not, however, involve by any means the same cost of construction. The cost of the Frith of Forth Bridge is not estimated to exceed half a million; whilst the Victoria Bridge, which had to be exported, as it were, to Canada, cost nearly a million and a half.

When completed (says the *Daily News*) the Frith of Forth Bridge will be to Scotland what the Britannia Bridge is to Wales—one of the wonders and attractions of the country. Its height, its great length, the character of its construction, and the beauty of the scenery at the points it touches, will present new inducements to tourists. It is anticipated that the work will be completed in less than than three years from the time that Parliament may grant powers for its commencement.

NOVEL SILK MACHINERY.*

LATELY, there have been introduced to the silk trade several novel machines which, though they have not hitherto obtained extensive use in this country, may prove useful aids to silk industry. One is a mode of winding the silk from the cocoon, and spinning it on the same machine. This has been done by Mr. Chadwick and others of Manchester, and beautiful work produced; but the difficulties in a new machine of turning-off a paying quantity of work, joined to the want of commercial facilities for obtaining from abroad an adequate supply of cocoons, has hitherto impeded the success of the experiment. Another is a mode of " sizing " or measuring the thickness of the silk thread, by passing it between two or more rollers nicely adjusted, and so arranged that when a part of different thickness occurs, the rollers move a system of levers which either stop the winding-on bobbin, or else transfer the thread to another bobbin. This operation is also accomplished by taking paper spools exactly alike in weight, and winding upon each of them a definite number of yards of silk, then with a delicate balance assorting them, placing those of like weight in distinct lots, and thus obtaining a number of spools with equal lengths and weights of silk to be put together on the doubling machine; for this matching is essential to the regularity of the twist in the silk spinning, as when threads of unequal diameters are "thrown" together it is very difficult to prevent its being unevenly done, and harder twisted in one place than another, or "corkscrewed," as it is technically called. At present, it is the office of a manager or operative of approved skill to " size " or match by the eye or touch the various bobbins of raw silk, before placing them on the spinning or doubling machines. To meet this purpose, there has also been invented in France a doubling system which, in place of taking several distinct strands or threads of silk, and winding them together as in the doubling machine first described, only deals with one thread of silk, which in an ingenious manner is doubled or rather tripled upon itself into three strands, by means of a traversing carriage like that of a cotton mule, putting at the end of each traverse a loop in the silk, doubling, and, thus, so to speak, matching the silk with itself, with the same view of attaining an improvement in the manufacture of the thread when twisted together. In the silk dye-house, a very useful machine from America has recently been introduced. To the present time, the silk, after being dyed, has been " stringed " or glossed by means of the severe hand labour of men twisting it in the hank with sticks to and fro, so as to rub the strands together, and produce the beautiful lustre so characteristic of the material; this required strong and skilful men, and with every exertion a workman could not finish much per day; but the machine in question entirely dispenses with the great physical exertions of the workman, and enables him to produce a larger amount of polished silk. This operation is performed in a box of cast iron with a steam-tight door, in which the silk can be placed on two rollers, the upper one adjustable to suit the varying lengths of the hanks, and the lower roller is fixed upon the head of a piston rod attached to a piston moving downwards in a steam cylinder; when the silk is placed upon the rollers, the door is shut, and the high-pressure steam is introduced, thoroughly saturating the silk; then by another valve the steam enters the steam cylinder, and the silk, whilst immersed in steam, is strongly stretched by the pressure applied to the piston; during the process, the silk hank is slowly revolved upon the rollers by gearing communica-

* Treatise on Mills and Millwork. By W. Fairbairn, Esq. London: Longman, Green, Longman, Roberts, and Green. 1863.

ting with the outside of the box, so that the shades of colour shall not be varied at those parts of the hank which bend round the rollers, and a few seconds suffice for the completion of several hanks.

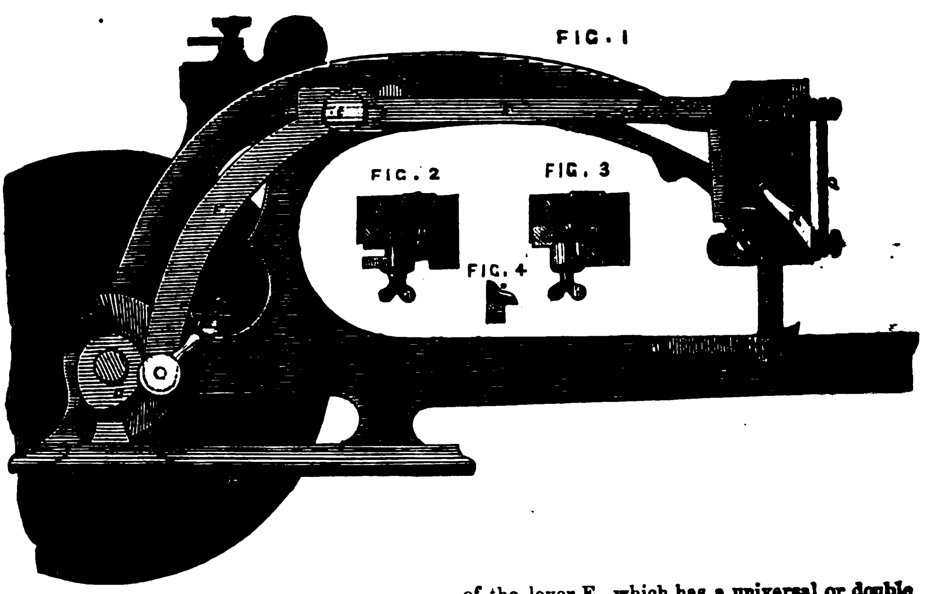
This class of machinery is, with slight modifications, adapted for the manufacture of sewing silks, warp and weft for piece goods, and for crape; but for inferior fabrics in silk the waste or spun silk is used, and this manufacture is very similar to that of flax or fine cotton. The waste silk from the cocoon-winding factories or the raw silk manufactories is combed or heckled, then cut into lengths of from 1¼ to 5 or 6 in., then placed in the opening machines, afterwards sewn up in small bags and boiled, to cleanse it from gum and other impurities, and after drying, is batted or opened with sticks like fine cotton; from this it is passed through breaker and finisher carding engines, drawing and roving frames, and mules constructed with rollers of spaces and adjustments, adequate for fibres of this length, when it is reeled and dyed as the raw silk before described.

M. GIFFARD AND AERIAL NAVIGATION.

M. Giffard, the inventor of the injector, has appeared in the field for invention opened up by aerial navigation. M. l'Abbé Moigno writes as follows on the subject:—"We have had the pleasure of spending some delightful hours recently with M. H. Giffard, and of receiving from him much valuable information which he has permitted us to transmit to the public. He believes that he has solved the problem of navigating the air. When the excitement caused by the success of his injector shall have ceased, and M. Giffard shall have recovered his *sangfroid*, he proposes once more to enter the arena with a cylindrical balloon, steam engine, and surface condenser. Setting out from the Champ de Mars, his aerostat, under perfect control, will make the tour of Paris and return to the Champ de Mars, as a racehorse sets out from the starting-post and returns there. M. Giffard, and those who have connected themselves with his scheme, state with certainty, that the motive power placed in the car will propel the balloon—supposing the weather calm or the breeze very slight—at the rate of thirty miles per hour—the average speed of a railway train. He adds, that the provision of coal and water carried by a balloon of moderate size, will suffice for a voyage of three days and three nights. The motive power will be a srew, but a sensible screw, one with large vanes, attached to the car and driven at a slow speed. Such a statement will surprise many; we may remark, however, that the inventor, since his last ascent, has not ceased to study those questions which are connected with the solution of the problem. He has tested every imaginable fabric, in the search for one sufficiently impermeable to permit him to use pure hydrogen obtained directly from water. He smiles when he sees men resort to heavy, thick, and expensive silks, while a double muslin, with an intervening thickness of black American india rubber, will do admirable service."

He states that he is "able to construct a steam engine whose weight shall bear a very small proportion to that of ordinary engines of equal power. The first machine constructed in the shops of M. Flaud, has already been worked with success at 900 lbs. per square inch; and M. Giffard has learned how to raise even this to as much as 3,000 lbs. on the square inch! This, in itself, is not enough; the quantity of water which can be taken up is necessarily very small, therefore the same water must be used over and over again. The public can see, if they will, in the Rue Jean Goujon, No. 27, a system of pipes, suspended just beneath the roof of a large workshop, which condense the waste steam from a 10-horse engine; every difficulty is thus provided for; and in the course of a very few months, we trust that successful experiments will solve every doubt respecting the success of M. Giffard's enterprise."

SMITH'S SEWING MACHINES.



SMITH'S IMPROVEMENTS IN SEWING MACHINES.

This invention, by G. H. Smith, machinist, of Ipswich, relates to the means of producing the feed motions of certain sewing machines known by the name of double or back action machines, and consists in the combination of a lever working on a universal jointed or double action fulcrum and actuated by a double tappet, on which lever is suspended from or near the end a feeder with a universal joint at the upper part, admitting of its being moved either forwards or backwards across the arm of the machine, or at right angles to such direction of motion, such feeder acting in combination with a double guide capable of being moved and set so as required to form a guide way for the feeder in either of its respective motions, and a bevel formed on the operating end of the working lever, or on the end of a fixed spring, and impelled by the said lever for the purpose of acting on a bevel formed on the feeder in order to produce the required motion of the same, either in the direction of the length of the arm of the machine by the one bevel sliding over the other, or in the direction across the arm by the pressure of one bevelled piece on the other. By means of this combination the feeder is worked through the several motions required for propelling or feeding the article to be sewed either across or up the arm of the machine by the agency of one lever instead of requiring two or more levers as usual, such lever having a fulcrum with a universal or double action joint, and being worked by a double tappet on the driving shaft.

Fig. 1 is an elevation of the machine at the side to which the lever and feeder are applied; fig. 2 is a horizontal section showing the parts of the lever, feeder, and double guide, in their respective positions; and fig. 3 is a similar section showing the same parts arranged so as to produce the motion of the feeder in the direction of the length of the arm. In these several figures the same letters of reference indicate corresponding parts.

A, A, is the ordinary frame or standard of the machine; B is the ordinary arm of the same; C is the driving shaft; D, D*, is a double tappet, whereof the edge of the part D is caused, by the revolution of the shaft C, to act on the lever E, in such a manner as to raise the feeder F, by raising that end of the lever E from which it is suspended, and the face of the part D* of the double tappet is caused to act on the lever E, so as to give the required horizontal motion to the feeder F, springs being applied both to the lever and the feeder for the purpose of returning them to their respective positions after the cams have respectively ceased to operate. G is the fulcrum of the lever E, which has a universal or double action joint (as shown on the drawing by dotted lines) on which the lever oscillates in such a manner as to produce the requisite feed motions. H is the operating end of the lever, which is formed with a bevel I, as shown in figs. 2 and 3, capable of acting on a correspondingly-formed bevel K, on the feeder F, for the purpose of moving the feeder, either in the direction of the length of the arm or in that across, according as the double guide L is in the position shown in fig. 3 or in that shown in fig. 2. The double guide L is turned on a pivot M by means of a thumb screw N, and secured either in the position shown in fig. 2, or in that shown in fig. 3. When it is in the position shown in fig. 2 it presents a stop to the movement of the feeder in the direction of the length of the arm B, but leaves an opening which admits of its movement in the direction across the arm by the pressure of the bevelled part against that of the feeder. And when the double guide is in the position shown in fig. 3 it presents a stop to the movement of the feeder F in the direction across the arm B, but leaves a space for the feeder to be moved towards the left hand in the figure or in the direction of the length of the arm by the action of the bevel I on the bevel K. Hence it will be seen that the required motions of the feeder F may be controlled and regulated by merely setting the double guide in the manner described, thereby obviating the necessity of displacing or changing the feeder when the direction of the feeding is required to be changed. O is the fulcrum or centre of suspension of the feeder; this fulcrum has also a universal or double action joint so as to accommodate the motions of the feeder to the motions of the lever E. Fig. 4 represents detached a horizontal section of the feeder showing the foot or presser at the bottom of the same, which, it will be observed, is formed with two members or claws, whereof one is adapted for feeding in the direction across the arm B, and the other in that of the length of the arm, the needle indicated by the small circle being similarly situated in relation to each of them. The bottom surface of the foot or presser is jagged or serrated in such a manner as to give it the required hold on the cloth or material to be sewed when worked in either direction. P is a vulcanized india-rubber spring for keeping the foot of the lever E in contact with the part D* of the double tappet as required when the bevel is formed on the end of the lever E. Q is another spring of the same kind for bringing down the opposite end of the lever E as required, after it has been raised by the action of the part D of the double tappet on the lever. R is a steel spring for returning to its position the feeder F after it has been acted upon by the lever E.

PAGE'S IMPROVEMENTS IN TAPS OR VALVES.

This invention, patented by Mr. John Page, engineer, Liverpool, comprises various improvements in taps or valves to be made in various materials, and to control the passage of fluids, such as water, gas, or steam.

In one arrangement of tap or valve a conical plug is employed, this plug working as usual in a conical chamber or body; the plug is however hollow, the fluid entering it by a side opening, and being discharged through one end of the plug made to project for that purpose, whilst the handle by which it is turned is fixed upon the other end. If a curved discharge is wanted, the projecting part may be curved round, or it may be cut off close to the body, and a spout be screwed or otherwise fixed upon the body; or the passage or piping may be continued in any convenient way from what may be termed the bottom of the tap body.

An important feature in this improved arrangement consists in the opening by which the fluid enters the hollow plug being carried some distance round the plug, instead of being parallel to its axis as in ordinary cases, the object of this improved arrangement being to permit of the tap being opened very gradually, and to render it in consequence suitable for high pressures.

Another modification, embodying the feature of a hollow plug with the opening round it, is well suited for the purposes of a hydrant. The plug in this case is an inverted hollow cup, into which the water enters from below, whilst the discharge is by a slot round a portion of the side into a curved discharge branch. The spindle of the plug or cup passes upwards through a stuffing-box or plain aperture, and is shaped externally to receive a key or handle for opening it by. Taps or valves of various sizes may be made in this way.

In valves or hydrants in which a disc valve-piece with a conical or spherical rim is made to close against an annular seat, through which the fluid passes when the valve is opened, the details for opening the valve-piece comprise, according to the present invention, firstly, a spindle projecting through an aperture or stuffing-box to receive a key or handle externally to turn it, but constructed not to move longitudinally; secondly, a screw into which the spindle is entered or with which it is otherwise connected so as to turn it and permit of its longitudinal movement; and, thirdly, a nut fixed inside the valve body, and through which the screw works. The valve-piece is attached to or forms part of the screw or screwed piece, and is moved to or from its seat by turning the spindle. The passage leading to and from the valve may be variously arranged, and so that the valve either closes against the pressure or has the pressure tending to keep it closed. Similar actuating details may be used in the case of sluice or sliding valves. In valves of this class the slide or sluice is on closing forced home with its extreme end projecting more or less into a small recess. This recess is very apt to get filled with dirt, so as to prevent the valves being properly closed; by the present invention, however, this inconvenience is prevented by forming a passage in communication with this recess in such a way that when the valve is open the fluid scours freely through the recess, and so removes any sediment.

Fig. 1 in the accompanying drawing is a vertical section of a tap constructed according to this invention. In this arrangement a conical plug 2 is employed, this plug working as usual in a conical chamber in the tap body 1; the plug 2 is however hollow, the fluid entering it by a side opening 3, and being discharged through one end of the plug 2, the smaller end in this example made to project for that purpose, and having a mouth-piece 4 screwed upon it in such a way as to hold the plug in its place in the tap body 1. A handle 5 is formed on, or it may be fixed on or applied to the other end of the plug 2. If a curved discharge is wanted, the projecting part of the plug may be curved, or it may be cut off close to or within the body, and a spout 6 may be screwed or otherwise fixed to the tap body 1; or the passage or piping 6 may be continued in any convenient way from the tap body. A sluice

Fig. 1.

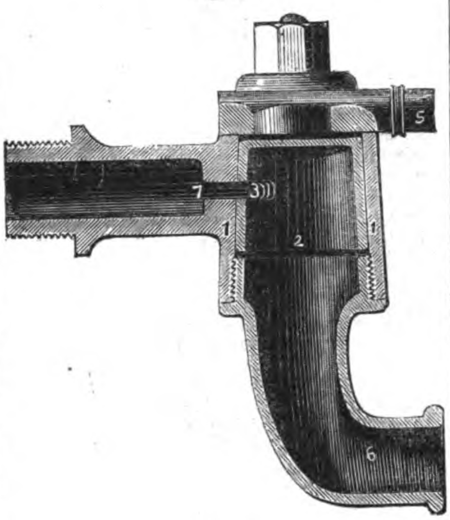


Fig. 2.

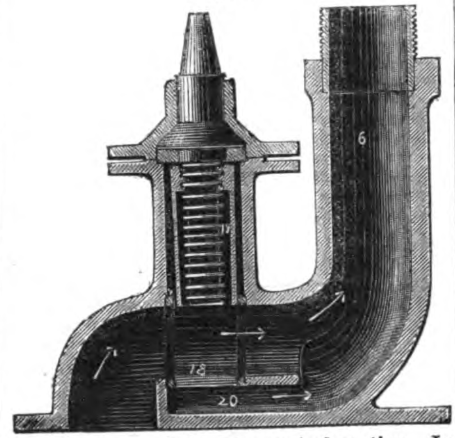


valve is shown at fig. 2 in vertical section. In valves of this class the slide or sluice 17 is on closing forced home with its extreme or bottom end projecting more or less into a small recess 18 opposite to the box 19, into which the slide is withdrawn when opened. This recess 18 is very apt to get filled with dirt so as to prevent the valve from being properly closed; by this invention, however, this inconvenience is prevented by forming a passage 20 in communication with this recess in such a way that when the valve is open the fluid scours freely through the recess 18 and passage 20, and so removes any sediment.

FOUNDRIES AND FOUNDRY ECONOMY.

It would well repay the venture of some enterprising capitalist to establish a model foundry in London. Iron-founding is now practised here after a very primitive and uncommercial manner. Not that finer casting can be had than those turned out by London houses, employing the best skilled moulders and the finest Charlton or Woolwich sand; for nowhere in the world can such founders' sand be found as that which may be purchased in the loam-pits within twenty miles of the metropolis. Excellent "work," whether it be that of the founder or mechanician, has long been procurable; for the best makers of our time cannot surpass the workmanship of the last century, so far as quality alone is considered. The great object, in these times, is to produce excellent work at a very moderate cost. This the London founders cannot do. We know from the practice of the Glasgow chair-founders that small castings (nearly one hundred separate pieces to the ton) can be profitably produced at from £4 to £4 10s. per ton, and in this case the whole of the moulding is done by hand. In other words, "moulding machines" are not employed. London houses have, of course, to meet heavier charges, every way, than prevail in the North. Iron is nearly or quite 10s. per ton dearer here than in the north, and so is coke. Wages are heavier also; but the difference, in these three important elements of foundry charges, does not account for the difference in the cost of turning out finished castings. We work, here, at a lower blast pressure, we burn more coke per ton of metal brought down, and in other ways incur greater expense. Many of the northern founders work with a blast of from 20 in. to 24 in. of water, whereas there are many founders here who do not go above 8 in. With small cupolas, say 22 in. in diameter, the higher blast permits of running off 5 tons an hour, while with the milder blast, 1 to 1½ tons only is reckoned fair with the same-sized cupola. In respect of fuel we know London founders who, paying 30s. a ton for coke, melt but 3 lbs. of iron, or, rather, make but 3 lbs. of finished castings per pound of coke, while in better worked establishments 6 lbs. to 8 lbs. of castings to 1 lb. of coke is not unusual. Hard blowing is, we believe, of great consequence in the economical production of casting. In blast furnaces, where the pillar of blast was once 1¾ lb. to 2 lbs. only per square inch, a great advantage, as we know, has been secured by the adoption of more powerful blast engines, working at 6 lbs., 7 lbs., and, in exceptional cases, even up to 10 lbs. per square inch. So in foundries; for a 22 in. cupola a Lloyd's fan, 36 in. in diameter, and making 1,400 to 1,800 revolutions per minute, is found to be much better than the old rule of employing a fan of the same diameter only as the cupola itself, and, working it, as was formerly practised, at a low speed. The construction of cupolas has, of course, much to do with economy of fuel. The old "churn" pattern, larger at the bottom than the top, gives no support to the charges, nor does it permit of the proper diffusion of the blast among the fuel. The Manchester practice, of which Mr. Ireland—a veteran foundry engineer—may be considered the father, is to make the cupola something in shape like a blast furnace, with boshes and a crucible or hearth below. Here, too, the blast is subdivided among ten or a dozen tuyeres, arranged in at least two rows. One of Mr. Ireland's cupolas, of which we have a drawing before us, is 4 ft. in diameter outside; the crucible is 22 in. in diameter; the boshes, enlarging to 33 in., are 22 in. high; and the whole height from the floor is 21 ft. The blast, brought in through two 9 in. pipes, is admitted into two annular cast-iron chambers built into the fire-brick lining, and conducted thence into the interior through a bottom row of three 6 in. tuyeres, and an upper row of eight 2½ in. tuyeres. The large lower tuyeres are about 20 in. below the bottom of the boshes, the upper or 2½ in. tuyeres, being exactly at the bottom of the boshes. All the tuyeres, eleven in number, have sight holes, closed by lids swinging upon pins, and there are valves to shut off the blast from either or all the tuyeres. In some of these cupolas, melting free running iron, 10 lbs. of metal, we believe, are run down per lb. of coke.

It is worth the while of our town founders to attempt the substitution of gas coke at 11s. per ton for the costly article of which Messrs. Straker and Love's, from the Brancepeth pits, is reckoned reasonable at 30s. A ton of gas coke is a ton of carbon nearly, and a ton of the best foundry coke, however free from sulphur, is no more. At one time it was thought to be wholly out of the question to burn "slack" under steam boilers. It went a begging at 4s. or so per ton, until at last some one made the attempt to burn it, after which it rose in price until, at last, it can hardly be bought, in London, under 11s. If it were attempted to burn gas coke in cupolas, smearing it, possibly, with chalk and water to secure a proper flux for the iron, it might result that our town founders would save at least one-

half of their present charges for fuel. The experiment, certainly, is worth making.

The "drop-bottom" is one of the essentials to a good cupola, which deserves to have been long since adopted here, as it is abroad. If a charge "sets," from want of blast, in a cupola, there is nothing to do but to tear down the whole affair, and even under the ordinary circumstances of working, "raking out" after drawing off a charge is a most laborious, and, indeed, severe operation. If, when a charge of iron has been run out, the remaining contents of the cupola could be quickly and quietly dropped into a pit below, the foundrymen, at least, would appreciate the saving of labour and of that slow process of broiling which necessarily attends a quarter hour's exposure to melted iron and hissing lava. The "drop-bottom," we find, is being at last adopted by some of our very best founders, who count largely upon the saving of labour, and the advantage which their workmen are likely to derive from its introduction. It has been said of the "drop-bottom" that the unexpected dropping of a cupola full of melted iron would be attended with great danger, and, furthermore, that the cost of making a new "bottom" at every charging would counterweigh every possible advantage to be derived from its use. As for dropping a charge, it could, at the worst, only fall into a deep pit, and this could only happen through the deliberate action of a workman, for the bottom should swing upon hinges of great strength, and it is usually held by a flat bolt, say 3 in. by 1½ in., passing through two very strong staples. As for making a fresh bottom at every charge, here is nothing of the sort. The cast-iron bottom, say 1½ in. thick, has a raised flange, curb, or cooming upon its upper surface, and within this cooming, 3 in. high or thereabouts, are bedded a quantity of fire-brick to the thickness of 4 in. or more, and these are so secured as to form an integral part of the bottom itself, dropping with it and rising again into their proper place. When the drop-bottom is locked in its place, therefore, preparatory to a fresh charge, there is only a little trimming with fire-clay or road-drift required to make a perfect joint all round; and this operation, we know, occupies an amount of time wholly beneath consideration.

An important opening for business—which the iron-founder should keep in view—is that for the production of malleable cast iron, the use of which is rapidly increasing. To many, the production of malleable cast iron is a profound secret; and we cannot deny that there are processes now practised among the makers of this material which are known only to themselves. Taking up the subject broadly, however, all malleable cast iron is, simply, cast iron partially decarbonized by exposure either to metallic oxides or to other substances having an affinity equal, or nearly so, to that of oxygen for the carbon contained in iron. Samuel Lucas, of Sheffield, was among the first (in 1804) to make malleable cast iron; and the specification of his patent, easily enough accessible, contains useful, and even interesting, particulars as to its production. From a communication, however, just read by M. Brüll before *La Societe des Ingenieurs Civils*, at Paris, it appears that the illustrious Reaumur, as early as 1722, having the curiosity to learn the possible truth of the workmen's tradition of a lost art of producing sharp and durable chisels from cast iron, undertook a series of experiments, which completely demonstrated the probable truth of this tradition, inasmuch as he actually produced iron which was both fusible and malleable. Let us here digress so far as to observe that the other day we picked up an old annealed cast iron wheel skid from among a lot of scrap in a founder's yard, and that, at our request, a smith succeeded, with some difficulty, in breaking off a piece. From this piece, which we still have by us, he also broke a smaller piece, which, after heating to a cherry red, or to the right heat for drawing copper, he drew into a chisel. This took the colours of steel when cooling from a like heat, and was hardened and ground, and we found it chip wrought iron rably well, while it kept an edge which would have answered very well indeed for many kinds of work in wood. Reaumur had but to partially decarbonize any hard and brittle cast iron, and he was certain to obtain, as we did, a very good chisel steel, not perhaps equal to Huntsman's, but still of useful quality. M. Brüll states that Reaumur, after many experiments, adopted a mixture of chalk and bone-lime *(chaux d'os)* with charcoal. The castings of white iron were heated in close crucibles, along with mixtures of this sort, until they were sufficiently decarbonized. As now made, malleable cast iron, although the subject of many improvements and secret processes, is produced by heating the castings slowly to a red heat while confined in closely luted vessels, and covered with hematite ore in layers. The heat has to be slowly raised, twenty-four hours being occupied in bringing on a red heat, while the decarbonizing process goes on, in some cases, for three, four, or five days longer. The metallic iron contained in the oxide employed sometimes melts and adheres to the surfaces of the castings undergoing treatment. The heat is in this case probably too high, and for this, if for no other reason, oxide of zinc is now in great repute as a decarbonizing agent among the American makers of malleable cast iron. It might be worth while to try black oxide of manganese for the same purpose, although we are not certain that this has not been already done. There are many processes for producing malleable cast iron, all alike, or nearly so, in principle, but different in detail. Messrs. McHaffie and Co., of Glasgow, are just now producing a quality which is attracting some attention, and their process, we believe, is a secret one. It would take but a moderate amount of intelligent experimenting, we apprehend, to find out what this secret is, and in the meantime it would be as well for some of our founders to attempt its discovery for themselves. If iron-founders are not, themselves, capable of operating so as to obtain immediately certain results, there is now an abundance of metallurgical talent only waiting their commands.—*Engineer.*

RAILWAY AND WAGGON GREASE.

THE grease or soap used for diminishing friction on the axles of carriages may be divided into two classes—one, ordinarily termed "locomotive grease," has tallow or fixed oils, or a mixture of both, for its basis, diffused through a weak solution of carbonate of soda; while the other, "antifriction" or "waggon" grease, is a soap of lime and rosin-oil, or certain cheaper substitutes mentioned below. This subject is of more importance than might at first sight appear; for while the grease-account of railway companies forms no inconsiderable item of their expenditure, the waste of motive power, and wear and tear of plant entailed by the use of an unsuitable grease, is enormous. The difficulties experienced from this cause have compelled the leading companies to manufacture their own grease, cost being a secondary consideration to uniformity of quality.

Locomotive Grease.

This is the only article suited for high velocities; it is invariably used for passenger carriages, and latterly for goods and mineral waggons when these are provided with axle-boxes. As ordinarily prepared, it is of a yellow colour, and of various degrees of consistence. In its preparation some makers use palm-oil alone, while others employ tallow also, the extra cost of the latter being more than compensated by a reduction of the *total* quantity of fatty matter employed, since a grease containing 35 per cent. of the mixed fats will go as far as another with 42 per cent. or 45 per cent. of oil alone. The grease richest in material is not necessarily the best or most enduring lubricant, the characteristics of which ought to be:—

1. A suitable consistency;
2. Good lasting power, attended with but little increase of temperature, even at the highest speeds; and,
3. The smallest possible residue left in the axle-boxes.

A grease which is too firm will remain comparatively solid in the box, and allow the axle to become hot; while, on the other hand, one too thin becomes exhausted by a few miles' running.

A few years ago, a series of trials was made upon two lines of railway, the grease under experiment being placed in locked boxes, and the number of miles travelled before replenishing, carefully noted; the minimum was 46, and the maximum within a few miles of 1,200. In the former case, the grease contained 30 per cent. of palm oil alone, and in the latter 35 per cent. of tallow and oil; while a grease containing 46 per cent. of material (almost entirely tallow) ran about 800 miles, being too firm, and deficient in cooling power. That which gave the best results became, after a few revolutions, gradually softened, from the axle upwards, to the consistence of very thick cream, and by continued upward and downward currents, maintained a comparatively low temperature until exhausted.

It is desirable that as little residue as possible should be left in the boxes; for which purpose the smallest available quantity of alkaline carbonate should be used; 1·10 per cent. to 1·20 per cent. actual soda, gives the best practical results; a smaller proportion fails to ensure consistency and durability. The soda is used in the form of crystals.

The Process of Manufacture is exceedingly simple; the fats are melted in a boiler and brought up to 180 degs. to 190 degs Fahr.; the water and soda-crystals are heated in another vessel to 200 degs. Fahr., and both run into a wooden tub, with constant stirring, which is continued at intervals until the mixture is cold. Slow cooling ensures a firm article, and large batches, which retain their heat for a considerable time, are therefore preferable. Care is taken, for obvious reasons, to avoid the introduction of sand or gritty matter. The proportions of materials vary in different establishments, and in the same establishments at different seasons of the year; the grease for July use being too firm for December, and *vice versa*; 25 per cent. is the lowest quantity of fat that can be safely used in the coldest weather, while 35 per cent. is amply sufficient for our warmest summer use; the following proportions have been used with excellent results:—

	Winter.			Summer.		
	cwt.	qr.	lbs.	cwt.	qr.	lbs.
Tallow...........	3	3	0	4	2	0
Palm oil	2	2	0	2	2	0
Sperm oil	0	1	7	0	0	27
Soda crystals ...	1	0	14	1	0	8
Water	12	3	12	12	0	26

These proportions produced one ton of grease (allowing 2½ per cent. for loss)—that marked "summer" ran 1,200 miles; the sperm oil, although small in quantity, has an excellent effect; but some makers, for economy, use rosin-oil instead, although the result is questionable.

From the foregoing remarks, it will be seen that a simple analysis of a fatty grease, although indicating cost of production, affords little or no test of its practical value, running power being the true and only criterion.

Antifriction, or Waggon Grease.

The greatly increased price of rosin, occasioned by the American blockade, has led to a diminished use of this article. It is well suited for low speeds; it was extensively employed for goods and mineral traffic when its cost was less than one-half that of locomotive grease; but now that the value is considerably greater than the latter, its use is confined to waggons having no axle-boxes.

This grease is of two kinds, with or without water; both should be free from lumps or gritty particles, smooth, and of such consistency as to be easily spread on the bare axle; the former should not part with its water when moderately agitated. The materials used are rosin-oil (obtained by distillation) and caustic lime in a very fine state of division: this latter is obtained by the well-known process of running milk of lime through a series of overflow tubes, in the last of which, receiving the finest particles, it is allowed to subside, and the precipitate drained on canvas

to a pulpy condition. If grease free from water is wanted, this pulp of lime is agitated with rosin spirit, which, seizing the lime, expels the water; the latter, floating on the surface, is run off, and a further quantity of spirit is added until the mass is reduced to a cream, when it is ready for use. If a watery grease is wanted, the finely-divided lime, without spirit, is simply used in a milky condition.

The Process of Manufacture consists in adding to any convenient quantity of rosin-oil, without the application of heat, either of the above preparations of lime, until the mixture begins to thicken, avoiding an excess, lest the grease should be too hard. The quantity of lime varies with the quantity of oil used; in the case of the finer grease, there is no gain in adding an excess, as the spirit is the most costly ingredient; a cream is therefore used; while for the lower qualities, the watery milk of lime is made very thin, so that, in some cases, as much as one-fourth of the bulk of oil is added. The materials are well stirred together for about fifteen minutes in a tight box or a barrel in which a shaft furnished with blades or stirrers is made to revolve. The grease thus formed is run into barrels or receptacles before it solidifies or "sets."

Any written directions for the preparation of this grease must necessarily be general rather than specific, as so much depends upon daily practical experience; a manufacturer when in doubt about a new oil or lime mixture, generally experiments upon a small quantity first, and is guided thereby in his operations on the large scale.

The present high price of rosin has compelled manufacturers to employ several cheaper substitutes for it, such as paraffin residues mixed with coal-tar, residues from candle-making, from cotton-seed oil, fish oils or footes, pitch oil, the heavier parts of the American petroleum, &c.; all these produce grease of a certain quality, but none with the lubricating power of rosin grease. —*Chemical Technologist*.

Legal Intelligence.

VICE-CHANCELLOR'S COURT.

Pepper and Another v. Myers and Another. —This was an application for an injunction to restrain the defendant from performing the celebrated "Ghost" illusion. The plaintiffs were Professor Pepper and Joseph Heath, of Liverpool, and the circumstances of the case were as follows (according to the plaintiffs' version):—Mr. Pepper, with one Henry Dircks, were the first inventors of "improvements in apparatus to be used in the exhibition of dramatic and other like performances," and in August, 1863, letters patent were granted, giving them exclusive right of using their invention for 14 years. The method by which the illusion is produced is as follows:—The nature and object of the invention is, by a peculiar arrangement of apparatus, to associate on the same stage a phantom or phantoms with a living actor or actors, so that the two may act in concert. The arrangement of the theatre requires, in addition to the ordinary stage, a second one at a lower level, hidden from the audience as far as direct vision is concerned; the hidden stage is to be strongly illuminated by artificial light, and capable of being darkened instantaneously, whilst the ordinary stage and the theatre remain illuminated by ordinary lighting. A large glass screen is placed on the ordinary stage and in front of the hidden one. The spectators will thus not observe the glass screen, but will see the actors on the ordinary stage through it as if they were not there; nevertheless, the glass will serve to reflect to them an image of the actors on the hidden stage when these are illuminated, but this image is made immediately to disappear by darkening the hidden stage. The glass screen is set in a frame, so that it can be readily moved to the place required, and it is to be set at an inclination to enable the spectators, whether in the pit, boxes, or gallery, to see the reflected image. The glass is adjustable, and it is readily adjusted to the proper inclination by having a person in the pit and another in the gallery to inform the party who is adjusting the glass when they see the image correctly. The hidden stage is capable of being closed at the top by trap-doors. When the trap-doors are closed actors on the ordinary or visible stage can pass freely to and fro above the lower or hidden stage. The ordinary stage and trap-doors are covered with green baize, or other dark material, so that when the trap-doors are opened, the audience, even those in the gallery, will not readily be able to perceive the opening. The actors, or objects corresponding with the phantom images which it is desired to represent to the audience, are strongly illuminated by the lime-light, or the electric-light, or other powerful illuminating means may be employed. This light must accompany the actor in any movement he has to make. The hidden stage and the lanterns may be mounted on a carriage on rails, so that when it is necessary for the phantom actor or object on the lower stage to be moved, the lanterns may be caused to move also, or the lanterns may remain stationary whilst the actor moves, provided the whole space through which he moves is sufficiently illuminated. The lanterns are to be provided with means for instantaneously extinguishing or making the light, and for reproducing it, so that the phantom may be made to disappear and reappear at pleasure, whilst the audience and the stage will be more or less lighted in the ordinary manner, according to the effects desired to be obtained. For this purpose, a board is employed which is capable of being raised into a position so as entirely to cut off the light from the hidden stage when desired, or an ordinary opaque shade attached to the lantern may be used for the purpose, or when using the lime-light the desired effects are caused by gradually or instantaneously (as the case may require) cutting off the supply of gases, and the phantom image may by any of these means be caused gradually or instantaneously to fade away. When the trap-doors over the hidden stage are open, the part thereof assists in hiding the lanterns and the opening from the audience. The part acts to screen the lanterns from the audience, and also to ensure that any actor or object on the hidden stage shall not accidentally appear above the level of the visible stage. The phantom actor, when standing on the stage, leans against the screen, which is inclined so as to be parallel with the glass screen, and is covered with black velvet or other dark material, as is also the stage, in order that no image of either the screen or the stage may be seen in the reflection. The glass screen is a large inclined sheet of plate-glass on the ordinary stage, of sufficient size to reflect the full length of the actors or objects on the hidden stage to the audience in the pit, boxes, and galleries of the theatre. The hidden stage is between the glass and the audience. The glass is mounted in a swing frame so that it may be adjusted to the angle required by screws, or ropes and pulleys, or otherwise. The glass is to be set at such an inclination as to bring the reflected image to the level of the visible stage. This will enable the spectators, whether in the pit, boxes, or gallery, to see the reflected image without any obstruction to the view above the footlights, and it will be visible from all parts of the house except those extreme positions which cannot command a view through the glass of that part of the stage where the image is reflected. The glass being in a swing frame the proper angle of inclination is ascertained experimentally by having persons in the different parts of the house to say when the image is shown to them correctly. The scenery is so disposed as to conceal the frame of the glass, and we prefer that the glass should be able to descend into an opening or box beneath the stage, in which case we counterbalance the glass and frame so that they may easily be raised into the position desired by means of a rope, by which, aided by the bolts, the glass is supported in the required position. In this case the glass may either be adjusted when screened from the audience, and remain in position during the scenes, or (the proper angle of inclination having been previously ascertained by experiment) the glass may be raised on to the ordinary or visible stage and placed in position whilst the scene is before the eyes of the audience, under a subdued light, without the movement being observed, for which latter purpose the top bar of the frame of the glass should be made very light, or be omitted altogether. This arrangement admits of an actor on the visible stage passing across the space which the glass is to occupy, and this he can do just before the appearance of the phantom; and then immediately the glass is run up, the trap-doors are opened, the actor or image on the hidden stage is illuminated, and the phantom appears. This arrangement will render it less likely that the audience should imagine that there is anything interposed between them and the actors, than if the glass plate remained permanently in position during the scene. The hidden or lower stage may be provided with a trunk or well-hole, up which an actor can rise; he will then appear as a spectre rising out of the visible stage. The lanterns may be provided with coloured glasses in order to heighten the effect. As the actors on the visible stage do not themselves see the spectral images, marks should be placed on the stage, or other indications made, in order that they may know the position which the spectres appearing to the audience are to occupy. In order to appear upright upon the visible stage, the actor or object on the hidden stage should be inclined so as to be as nearly as practicable parallel with the surface of the glass. In effecting this, assistance is afforded by the screen of the hidden stage. Several sheets of glass may be employed at the same time, if one is not of sufficient width to cover the different parts of the stage at which it is desired that the spectre should appear, the interval or junction being concealed by the introduction of a tree or column, or some other piece of scenery.—The injunction was granted.

The case of Spencer v. Jack was heard before the Lord Chancellor on Friday, at Lincoln's-inn. This was an appeal from an order of the Master of the Rolls. The plaintiff was an engineer at Newcastle, and in July, 1860, he took out a patent for an improved method in condensing steam for working steam engines on board ships. It appeared from the specification that the plaintiff claimed as his invention a new combination of well-known matters—namely, surface and jet condensers of steam, which produced new and valuable results. The bill was filed to restrain an alleged infringement of the patent of the defendant's engineers at Liverpool, and, upon the application to the Master of the Rolls for an injunction, his Honour directed issues at law to try whether the patent of the plaintiff was a new and useful invention, whether it had been sufficiently described in the specification, and whether there had been any infringement of it by the defendants. The jury found in favour of the plaintiff on all the issues, and an application for a new trial was made to the Master of the Rolls on the following grounds:—First, that there had been a misdirection of the Lord Chief Justice of the Common Pleas; second, that the verdict was against the evidence; third, that there had been a miscarriage; and fourth, that the defendant had been taken by surprise. The Master of the Rolls granted a new trial, and, upon appeal from that order to the Lords Justices, their Lordships suggested that the matter should be brought before the Lord Chancellor, which was accordingly done.

Mr. Baggallay and Mr. Rigby, with Mr. Streeton and Mr. Webster (of the Common Law Bar), were for the plaintiff, appealing; Mr. Bovill (of the Common Law Bar), Mr. Selwyn, and Mr. Druce, for the respondents.

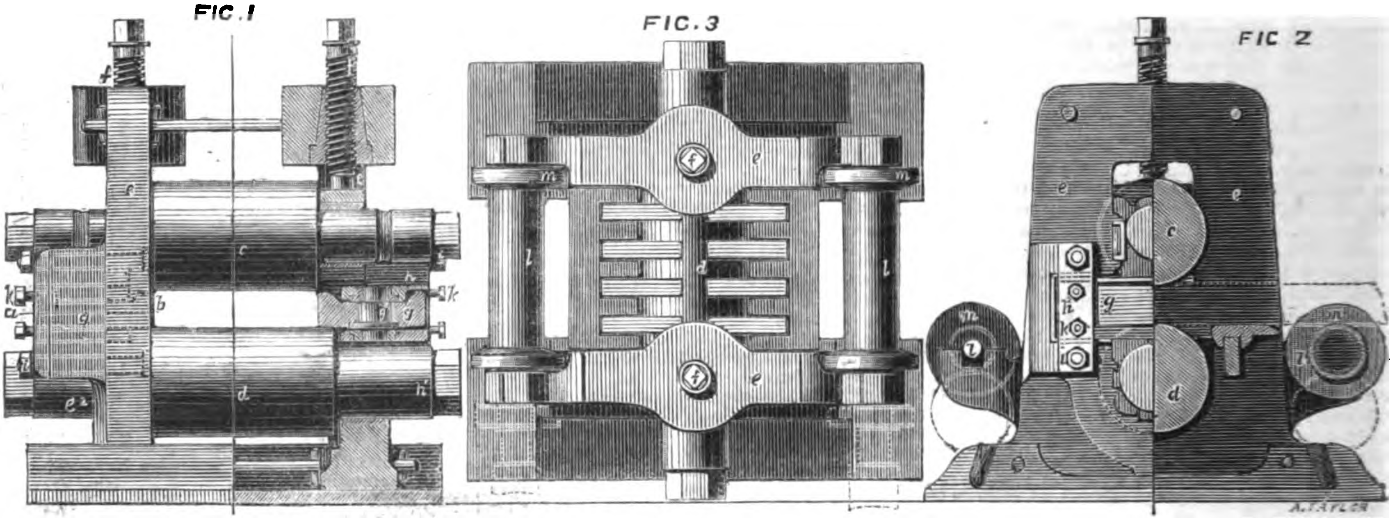
The case was resumed on the 25th.

The Lord Chancellor, in delivering judgment, said he was of opinion that the improvement of the plaintiff was the subject-matter of a patent, and, therefore, that his claim to the patent in question was well founded. With respect, however, to the alleged infringement of it by the defendants, he was unable, from the plaintiff's own specification, to find that there had been any violation of it. The bill must be dismissed without costs, and, as a consequence, the order of the Master of the Rolls must be reversed.

LAUNCH OF A FRENCH FRIGATE.

A colossal iron-coated steam frigate, called the "Numancia," was launched on Thursday last at La Seyne, near Toulon. This leviathan is an iron frigate completely plated over a teak sheathing, and carries 40 guns of the largest calibre in a covered battery, besides some pieces *en barbette* on her upper deck. She is to be rigged as a sailing frigate, and her masts, of a single piece, were brought from the forests of California. Her engines are nominally of 1,000-horse power, but the power may be increased to 4,000-horses. Her coal-bunkers contain 1,000 tons, and her crew will consist of 700 men. Her length on the deck is 288 ft her breadth 52 ft., her draught of water She is supposed to be the largest iron-coated f afloat. Her iron plates are 13 centimetre and weigh 1,300,000 kilogrammes. Her has been tried against the heaviest shot, supposed to be bullet proof. Notwithstan great weight, which exceeds 7,500 tons, pected that this frigate will possess extr speed and great facility of manœuvring, i quence of the immense power of her scr as from her admirable lines. The "Nu was only sixteen months on the stocks.

HARRIS, BUTLER, AND FRASER'S IMPROVEMENTS IN ROLLING ARMOUR PLATES.



HARRIS, BUTLER, AND FRASER'S IMPROVEMENTS IN MACHINERY FOR ROLLING ARMOUR PLATES.

Letters Patent have been recently granted to Messrs. Harris, Butler, and Fraser, iron manufacturers, for improvements in rolling armour plates. These improvements consist in constructing and arranging rolls in such a manner that lateral pressure is applied to plates and bars of iron during the rolling process, and the plates or bars are fed to and conducted from the rolls in a simple and expeditious manner. The patentees make the upper roll of the pair of rolls somewhat shorter than the lower roll, so that the lower roll projects at either end beyond the ends of the upper roll. A recess is made in each of the standards carrying the rolls, these recesses being at about the level of the acting surfaces of the rolls. In each of the recesses a rotating circular collar is placed, the collars rotating on vertical axes. The lower face of each collar rests on the cylindrical surface of the lower roll, and the cylindrical surfaces of the collars bear against the ends of the upper roll. When a plate of iron is passed through the rolls, the edge of the plate is prevented from spreading laterally by the rotating collars, and the edges of the plate are subjected to the same pressure, or nearly the same pressure, as the other parts. The upper roll can be raised or lowered without interfering with the rotating collars and lower roll. To roll plates or bars of any required width, it is only necessary to employ an upper roll having a length equal to the width of the plates to be rolled, the rotating collars being adjusted so as to bear against the ends of the upper roll. The lower roll being always longer than the upper roll, does not require to be changed on changing the upper roll. The rotating collars are adjusted by means of screws acting on their bearings in the recesses in the standards. The plate or bar is guided to and from the rolls by means of rotary guide rolls provided with sliding flanges, so as to accommodate plates or bars of different widths.

Fig. 1 represents, partly in front elevation and partly in vertical section, rolling machinery constructed according to this invention for rolling armour plates, bridge plates, boat plates, and other plates and bars of iron; fig. 2 represents the same, partly in end elevation and partly in transverse section; and fig. 3 is a plan of the same with the top roll removed. *c*, *d*, are the pair of rolls working in bearings in the standards *e*, *e*, the bearings of the upper roll being acted upon by the screws *f*, to adjust the distance between the rolls in the ordinary manner. The upper roll is shorter than the lower one, the lower roll projecting on either side the upper roll, as best seen in the sectional portion of fig. 1. On the outer sides of the standards, and near the level of the acting surfaces of the rolls, are projecting boxes e^2, in which boxes recesses are made, extending through the standards. In these recesses are the rotating collars *g*, and their gearing. The collars turn upon axes g^2, the bearings of the axes being carried by the frame *h*, and the frame *h* and collars *g* are adjusted in the following manner:—On either side, and in front of the recesses in the boxes e^2 and standards *e* vertical bars h^2 are fixed, the said bars being secured to the standards by the screw pins and nuts *i*. In the bars set screws work, the ends of which set screws bear against the frame carrying the rotating collars, and keep the said rotating collars to their bearing against the ends of the upper roll. The lower face of each of the rotating collars rests on the cylindrical surface of the lower roll, and the cylindrical surfaces of the said collars bear against the ends of the upper roll. By means of the rotating circular collars, the edges of the plate or bar being rolled are prevented from spreading laterally. Great density and uniformity and excellence of quality in the rolled plate or bar thereby results, and a rolled and skinned edge obtained, which is very desirable for rivetting purposes. When a plate or bar is required to be rolled of a width greater or less than the width of the upper roll, it is only necessary to change it for one having a length equal to the width of the plate or bar to be rolled. The lower roll being always longer than the upper roll, does not require to be changed on changing the upper roll. On changing the upper roll *c* the rotating collars *g* are adjusted against the ends of the newly-introduced upper roll by means of the set screws *k*, *k*. The upper roll can be raised or lowered in the standards by means of the screws *f* without interfering with the rotating collars and lower roll. By the use of guide rolls *l*, *l*, the plate or bar is carried into and from the rolls without the aid of manual labour.

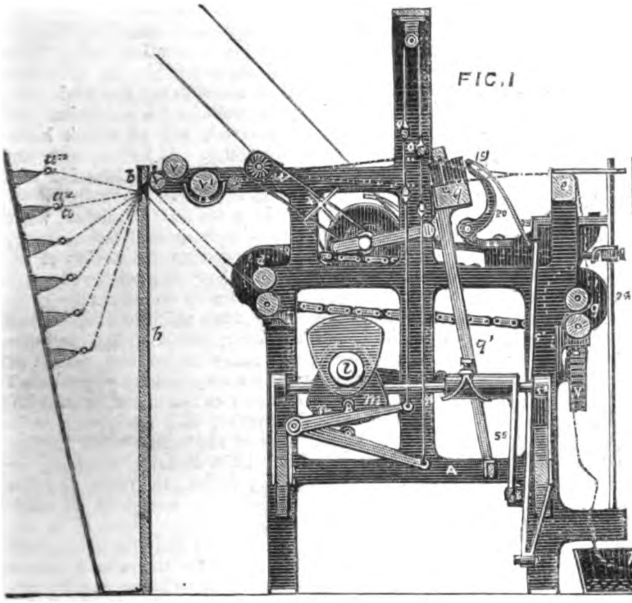
NARROW GAUGE LOCOMOTIVE.

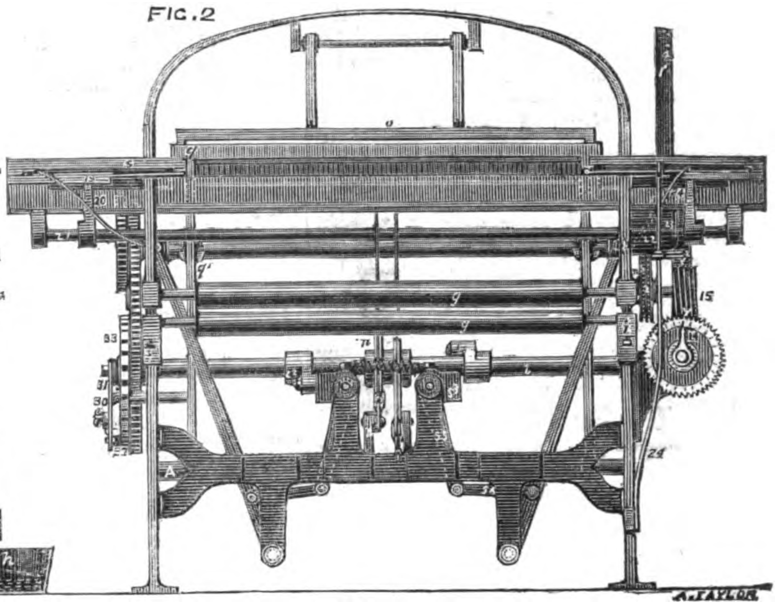
We have, on more than one occasion, pointed out the feasibility of substituting the locomotive for horse-power on almost any existing line, worthy of the term railway, to be found in the mining districts—as in example, the following bear a great deal of interest:—In 1836 a railway, 13½ miles in length, was opened between the slate quarries of Festiniog and the shipping port of Port Madoc, which gradually led to an increase of the shipment of slates from 12,000 tons to 64,000 tons per annum. This railway is on a guage of only 2 ft., and was constructed at a cost of £2,000 per mile. The whole line is a descending one, with several heavy gradients and sharp curves, and was for many years worked at a heavy expense by horse-power—the loaded slate waggons descending by their own weight, and carrying down with them, in boxes made specially for the purpose, the horses which were to bring up the empty trucks. But the use of horse-power came to be felt as an impediment to the further development of the traffic; and accordingly several engineers of eminence, and among others the late Robert Stephenson, were from time to time consulted as to the possibility of employing locomotive power. The invariable answer, however, was that it was impossible to construct a locomotive engine with sufficient power to work such a line with safety and efficiency. The project, nevertheless, was never altogether abandoned, and it has at last been successfully carried out by a young engineer, Mr. Charles Mendes Holland, to whom the dilemma of the company was fortunately made known. The plans furnished by this young gentleman, who is scarcely twenty-one years of age, and has just completed his apprenticeship, were submitted by the directors to qualified persons, and having been by them pronounced feasible, were placed in the hands of Messrs. England and Co., of London, for realization. As already stated, the result has been most successful. At the trial trip, the train accomplished the distance up hill from the port to the quarries in little more than an hour, and the railway has since been in operation as a locomotive line. About three miles from the quarries a small-bore tunnel, three-quarters of a-mile in length is felt to be somewhat disagreeable by passengers, but forms no impediment to the mineral traffic. The special character of the engine lies, we believe, in throwing the weight as low as possible. At the dinner which celebrated the running of the first engine, the impossibility of working any gauge by steam-power, was spoken of by Mr. England as an exploded fallacy. At all events, it might be well worth the while of mineral proprietors, and of the inhabitants of remote Highland districts, to satisfy themselves whether their wants could not be economically met by railways and locomotives after the model of those of Port Madoc.

RESERVOIR PAINTING-BRUSH.

Messrs. Crowden and Garrod have recently patented a painting-brush, the advantages of which, in comparison with the usual kind, is that it is made of first-class bristles selected for the purpose; its shape is nearly flat, and set in thin copper binding, and firmly cemented; it uses evenly, and in one way; and is made to deliver the colour with regularity on the work. The most remarkable feature of the invention is, that the centre of the brush forms a small chamber for the paint, which is worked up to the flag or top of the brush by the arrangement of the bristles, which are so placed to effect this purpose, that, while the brush is in use, it is working the colour to the surface and never becoming clogged. In flatting and stippling, so great an advantage of laying the colour with smoothness, will and must be appreciated by every decorator.

BARLOW'S LOOMS FOR WEAVING.



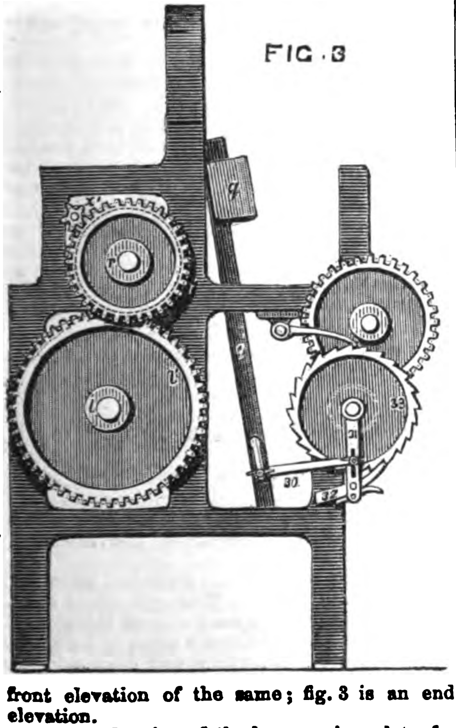


The workman using one of these brushes, will be enabled to cover one-half more space, use less colour, and produce a better result on the work in the same amount of time.

BARLOW'S IMPROVEMENTS IN LOOMS FOR WEAVING.

THE nature of this invention, patented by Mr. H. B. Barlow, Manchester, consists in supporting the bobbins containing the warp yarns or threads by a plate connected to or forming part of the loom, and in guiding the said warp threads direct to the loom, whereby facility is afforded in piecing up a broken end; and also in sizing and dressing the warp before it passes through the healds; and in an improved arrangement of parts for giving off or delivering the warps and for taking up the woven fabric.

Fig. 1 is a sectional elevation of a loom constructed according to this invention; fig. 2 is a



front elevation of the same; fig. 3 is an end elevation.

A is the framing of the loom; *a* is a plate for supporting the bobbins containing the yarn or thread for the warp; the plate *a* is in a slanting position, and the bobbins are placed in regular rows. Each warp thread passes through a hook a^1, fixed in the rods a^*, supported by the studs a^2; as each hook is in line with a bobbin it is evident the bobbins will be unwound regularly. The warp threads pass through the plate *b*, supported by the upright b^1; the plate *b* may have the requsite number of holes for the warp threads, or a rack or a comb may be used; the threads are thus kept separate, and if one breaks it can easily be pieced up without loss of time; whereas in ordinary looms, when a warp thread breaks, the loom has to be stopped to repair it. From the plate *b* the warp threads pass between the unwinding rollers *d*, *d*, which are covered with india rubber, leather, felt, or other suitable substance to give the requsite friction, or they may be grooved or fluted and covered with cloth. The warp passes under the lower roller *d*, and then between the rollers *d*, *d*, from whence it is taken to the sizing and dressing apparatus, consisting of the guide rollers *v*, *v*, the sizing roller v^1, which revolves in the size trough 12, and the two roller brushes *w*, *w*; these brushes remove the excess of size from the warp threads, and the fan *x* dries them before they enter the healds *o*, *o*. The fan is driven by the pinion x_1, see fig. 3. From the healds the warp passes through the reed of the lay, and thence to the breast beam *e*, in the usual manner; the woven fabric is taken up by the rollers *g*, *g*, and deposited in a receptacle *h*. The taking-up rollers *g* are similar to the unwinding rollers *d*; the upper roller of each pair revolves in stationary bearings, and they are turned round simultaneously by the chain 2 passing over the chain pulleys 1, 1, or by toothed wheels if preferred. Each chain pulley is connected to its roller by a set screw m^3, which can be slackened when required to change the position of the roller for tightening the warp. The lower rollers revolve in bearings *i*, fixed to the framing A; the set screws 3, in the bearings *i*, are to press the rollers together. As the fabric is woven and at each stroke of the batten the taking-up rollers are moved by the link 30, see fig. 3, connected at one end to the lay sword and at the other to the suspended lever 31, to which is jointed a catch, taking into the teeth of a ratchet wheel; the fabric is thus taken up as fast as it is woven by the rollers *g*, *g*, and the warp is delivered at the same speed by the rollers *d*. The tappet shaft *l* transmits motion by the tappets *m* to the treadles *n* and healds *o*, which are made in the usual manner. The lay *q* is connected to the lay swords q^1, which are worked by cranks or eccentrics on the shaft *r*. The shafts *l* and *r* are connected by the wheels l^1 and r^1, and the latter is driven by strap and pulleys as usual. The picking motion consists of the picking sticks s^*, actuated by the levers s^2, on the tappet shaft *l*. The bowls on the levers s^2 act on the wipers *ss*, fixed to the vibrating shafts s_1; to each wiper is cast a lever s^5, connected by the links s^6 to the picking sticks. The shuttle, in passing from one shuttle box *s* to the other, acts on a stud 18, against which press the springs 19, acting on the bent arms 20, fixed to the stop rod 21, connected as usual to the batten. The stop rod has the usual stop finger for acting on the slide or frog and spring starting lever, when the shuttle fails to box. The length of fabric woven is measured and indicated by a worm on the axle of the top roller *g* gearing into the wheel *y*, which is furnished with a dial 14. The circumference of the roller is fixed to one-fourth part of a yard or other determined length. By means of these improvements the ordinary operations of winding and warping are dispensed with, the warp threads passing directly from the bobbins to the loom at a uniform tension, thus ensuring great regularity in the work produced.

MANCHESTER BOILER ASSOCIATION.

AT the last monthly meeting of the Executive Committee of this Association, held at the offices, 41, Corporation-street, Manchester, on Tuesday, November 24th, 1863—the President, William Fairbairn, Esq., C.E., F.R.S., in the chair—Mr. L. E. Fletcher, chief engineer, presented his Monthly Report, of which the following is an abstract:—

"During the past month there have been examined 238 engines and 381 boilers. Of the latter, 17 have been examined specially, 9 internally, 55 thoroughly, and 300 externally, in addition to which 1 of these boilers has been tested by hydraulic pressure. The following defects have been found in the boilers examined:—Fracture, 10 (1 dangerous); corrosion, 25 (5 dangerous); safety valves out of order, 1; water gauges ditto, 30 (3 dangerous); pressure gauges ditto, 5; feed apparatus ditto, 2; blow-out apparatus ditto, 15 (1 dangerous); fusible plugs ditto, 3; furnaces out of shape, 12 (3 dangerous); over-pressure, 3 (1 dangerous). Total, 106 (14 dangerous). Boilers without glass water gauges, 3; without pressure gauges, 45; without blow-out apparatus, 48; without back pressure valves, 72.

"An illustration has lately been met with of the importance of removing portions of mid-feather walls, in order to give an opportunity of examining the plates. On this being done at

the instance of this Association, in the case of a boiler lately put under its care, the bottom, although presumed by its owner and engineer to be perfectly sound, was found to be nearly eaten through by corrosion, and on the very point of rupture, as in the case of No. 39 Explosion, the details of which are given below.

"Instances continue to be met with of serious corrosion, arising from the leakage of bolted joints concealed under brickwork. It cannot be too often repeated that all connections to boilers should be made by means of fitting blocks rivetted to the shell, excepting only the attachments to the front end plate, where they are not absolutely necessary, since the plate being flat the joints are more easily made, while at the same time, from their position, leakage, should it occur, is at once apparent. The front end plate should be left completely open, and not, as is too frequently the case, covered in with a wall of brickwork, since leakage—so prone to occur in the neighbourhood of the furnace mouths—is found to go on behind the brickwork undetected. A case of this sort has just been met with, where a plate was completely eaten through before the corrosion was known.

"EXPLOSIONS.

"No. 31 Explosion occurred at a distance of nearly three hundred miles, and as full details could not then be obtained, the fact of its occurrence was merely entered at the time in the tabular statement. The boiler was not under the inspection of this Association, and it has since been ascertained that it was of plain Cornish construction, having a single flue parallel throughout; its length being 25 ft. 3 in., its diameter in the shell 5 ft. 7 in., and in the flue 3 ft. 5 in., while the thickness of the plates was three-eighths of an inch, and the pressure to which the safety-valves were loaded, 40 lbs. Such a flue, on account of its large diameter, was unsafe from the day on which the boiler was made, though it might easily have been made secure by adopting any of the well-known plans of strengthening flues, among which may be mentioned, hoops, whether of T-iron, angle-iron, or bridge-rail section, as well as flanged seams.

"Six explosions have occurred during the past month, resulting in the death of eleven persons, and serious injury to eighteen others. Not one of the boilers in question was under the inspection of this Association. One of these exploded boilers, No. 39, has been personally examined, while this was prevented in other cases by distance, some of the explosions occurring upwards of two hundred miles from Manchester. It is expected, however, that detailed particulars of all of them will be obtained, while I am already indebted for a minute report on Explosion No. 38, to the kindness of an engineer residing in its locality, and who made an examination shortly after the occurrence.

"No. 38 Explosion, from which one man was killed, occurred to a boiler not under the inspection of this Association, and which was in use at an ironworks.

"The boiler was of plain cylindrical egg-ended shape, externally-fired, and connected by its steam-pipe to two others of different construction; all three collectively working an engine and forge hammer in the rolling mill. The ordinary working pressure of the boiler was 40 lbs., its length 35 ft., and its diameter 6 ft. 5 in., while the plates were of the most unusual and unnecessary thickness, of from nine-sixteenths to five-eighths of an inch.

"It is more difficult to make good work in a boiler with such thick plates, and it is reported that the joints in the present instance were imperfectly closed—that there had been unfair use of the drift, than which few things are more prejudicial to the strength of the boiler—that but few of the rivets were properly laid up, while, in addition, the overlap of the plates at the seams of rivets was unusually wide, and, in short, that the work was altogether most clumsy and inferior. Added to this, the boiler had been repaired over the fire more than once, with plates one-eigth of an inch thinner than the rest, while ...udinal seams of rivets, six feet long, were allowed to fall within the furnace, their original length having been increased by the repairs.

"The boiler had been leaking at the seams in the furnace for three weeks previous to the explosion; and in order to stop this the fireman had been in the habit of putting a bucket-full of sharps as well as a bucket-full of horse manure into the boiler once a week.

"The state of the boiler after the explosion afforded no indications either of overheating from shortness of water or of corrosive action, while there appeared to have been little or no incrustation; but it was found that the shell had rent at one of the longtitudinal seams over the fire, just where the thick old plates had been patched with the comparatively thin new ones. The rent extended throughout the whole length of the seam, and then ran into the transverse ones which crossed it at both ends, completely severing from the remainder of the shell the dome or egg-end. The latter was blown to a considerable distance, while the former, though lifted off its seat, was only thrown a few feet from it.

"The cause of the explosion was made a subject of scientific investigation at the order of the coroner, and the view given in the report thereon by the engineer engaged, may be briefly stated as follows:—

"The explosion was considered to be due to excessive pressure of steam, a pressure greater than that at which the boiler was ordinarily worked, and which it was thought might have arisen in the following way:—The explosion occurred shortly before four o'clock in the afternoon, the boiler having been cleaned out the same morning, while the other two to which it was connected were working alongside meantime. In order to clean this boiler out while the others connected to it had their steam up, it was necessary that the junction valve should be closed, and if this valve had not been re-opened, as it ought to have been, as soon as the steam was up—then in the event of the only safety valve with which this boiler was fitted, either sticking fast in its seat, or being tampered with—the steam would be bottled up, and the pressure continue to rise, without giving any sign until actual explosion resulted, since there was no steam guage upon the boiler.

"One or the other of these two conditions it was concluded had occurred—viz., either that the safety-valve had stuck fast in its seat, or had been intentionally tampered with, at the same time that the boiler was isolated from the other two by the junction valve being shut down.

"The supposition of the junction valve having been left closed was, it was thought, strengthened by the fact that the steam had been so low a few minutes previous to the explosion, that both engines had to be stopped, so that had the boiler in question been then in connection with the others, it was argued that the rupture must have taken place when the pressure was lower than usual, which was not thought likely. That the safety-valve had stuck fast in its seat, was considered most improbable, while the supposition of its having been intentionally tampered with derives support from the reckless character of the fireman, who, shortly after the explosion had occurred, was known, while tending the boiler alongside the exploded one, to have gagged his alarm whistle on it signalling shortness of water; in consequence of which a number of workmen engaged near the boiler deserted their post, stating that they considered their lives in danger.

"The jury dissented from these views, and brought in a verdict of accidental death, adding —'That in their opinion the boiler did not explode from excess of steam, but from a combination of gases occasioned by the lifting of the junction-valve when there was not a sufficient pressure of steam. The consequence of the junction-valve being opened under these circumstances, would be, that the steam would rush into the boiler from the adjoining ones, and, by generating gases within it, blow it up.'

"The opinion of the jury can scarcely be regarded as otherwise than hypothetical, and as being entirely unsupported by experience.

"The view that the boiler exploded from excessive and unusual pressure, consequent upon the safety-valve and junction-valve being both closed at the same time, is thought to be an unnecessary supposition, considering the workmanship of the boiler, as well as its condition and the treatment it received, all of which have been previously described. A boiler, roughly made as this was, of plates of excessive and varying thickness, having an unusually wide overlap, and being in a leaking condition, with its seams choked up with bran and horse dung, such a boiler when exposed to the action of an external fire would be utterly untrustworthy, and the mere pressure of steam by no means the only element of weakness. Such thick plates, unless most kindly laid together, would be fighting one against another, especially under the action of the fire, when unequal expansion, aggravated by the varying thickness of the metal, would be sure to ensue. Moreover, had the pressure in the boiler at the time of explosion been higher than that at which it ordinarily worked, or indeed equal to it, viz., 40 lbs., the main portion of the shell would never have remained so near to its original seating as it did, and thus the position of the fragments can only be accounted for by the supposition that the steam was low at the time of explosion, which is borne out by the fact that there was not power enough to drive the engines, and they were stopped in consequence.

"This explosion, therefore, can only be regarded as an additional illustration of the dangerous character of the externally-fired boiler, especially when improperly repaired and carelessly attended to. The constant allusion to such cases may be tedious; but the subject is only recurred to on the repetition of explosion; and it is trusted that the persevering statement of these facts will assist in removing from general use so dangerous a class of boiler as those externally-fired have proved theselves to be.

"No. 39 Explosion, which was attended with the death of one person and injury to four others, occurred to a boiler working at a cotton mill, and not under the inspection of this Association.

"The boiler, which was fifteen years old, was of plain double-flued construction, internally-fired, and of the class termed Lancashire, its length being 32 ft., its diameter 8 ft. in the shell, and 3 ft. in the flues. It worked alongside of another boiler very similar to itself, and to which it was connected.

"The boiler had rent at the bottom of the shell, immediately over the mid-feather wall on which it had rested. This rent, which may be termed the primary one, extending longitudinally for about two rings of plates, and then assumed a transverse direction, running completely round the boiler and severing an entire, though rather irregularly-shaped, belt from the shell. The front end plate was separated from the other part of the boiler, while the furnace tubes, which appeared perfectly sound remained attached to the rest of the shell, which had been thrown out of its original seat and turned bottom upwards. The longitudinal stays for stiffening the end plates, though massive, were curled up into a scroll, and the transverse ones, which should never be introduced in a cylindrical boiler, proved, as might have been expected of no assistance in strengthening the shell.

"The damage to the surrounding property was serious, a considerable portion of the mill being unroofed, and one of the side-walls blown down, while the boiler-house was reduced to a heap of ruins.

"As to the cause of the explosion there can be no question; there was no evidence of shortness of water, the furnace crowns being uninjured; but on examining the edges of the plates at the primary rent, which had occurred over the mid-feather wall, their thickness was found to have been so reduced by external corrosion as not to exceed that of a halfpenny piece.

"In the scientific evidence given at the in-

quest, the plan of setting boilers upon mid-feather walls was strongly condemned, and the corrosion so frequently induced, and at the same time treacherously concealed by them, clearly pointed out. Of the truth of this there can be no question; and it is difficult to say anything more upon the danger of these mid-feathers than has already been said in previous reports, while the occurrence of the explosion in the present instance affords an additional illustration of the correctness of the views so frequently expressed.

"The jury considered that this explosion would have been prevented by due precaution on the part of the owner, and therefore brought him in guilty of manslaughter."

NOTES FROM THE NORTHERN COLLIERIES.

No. II.

COLLIERY ENGINE BEAMS.

SUCH appear to have been *the facts*, with respect to the circumstances of fracture of the Hartley Colliery engine beam, as given in our last part. The question is, what broke it? Every one must see how important a practical question it is, in any view of the subject; but should it turn out that there is great doubt that the true cause of fracture has ever yet been discovered, it will be agreed that this is a practical question still deserving of the most careful discussion. For we shall profit but little by an accident so grave and terrible in its results, if we remain satisfied with any *ex cathedra* explanation, which may not bear the test of exact examination, and which therefore would in such a case be likely only to mislead, as to any constructive modifications that might be hereafter based upon it.

Several guesses were, at and directly after the time of the accident, hazarded, with more or less show of probability, to account for the fracture; some of these we need not repeat. Amongst the more notable of the remaining, were those which attributed the fracture to simple dead working pressure, long continued, upon a beam never adequate safely to its increasing load. One was that which attributed the *first commencement* of fracture to the fall of the beam, a few days before the accident, from off the screw-jacks, back on to the centre bearings, while new brasses were about being put in, and that the final smash was only the gradual enlargement of the original crack. Another was that the centre bearing shaft had been keyed in, with its 24 taper keys, needlessly and dangerously tight, and that the effect of the difference in contractility between the beam and the centre bearing, shaft and keys, affected by the intense severity of the winter cold, had been to produce a bursting strain at the centre of the beam, that left very little to be done by a load or blow, in order to break it off short across. A fourth assumed that one or both pump buckets in the pit shaft had got wedged somewhere about the middle of the stroke, and that the beam was broken by the sudden arrestation of its movement as the engine was going indoors.

For the present, we may dismiss all these, as having none of them sufficiently taken account of the actual facts, and indeed not received any general assent, and take the official declaration of Mr. Blackwell's Report to the Home-office, as containing the accepted dogma as to *how* the accident was produced, and then consider whether the conclusion enunciated in that report be sustainable or not, when examined by the rigid rules of dynamics.

To whatever result the investigations may ultimately lead us, we must not be misunderstood as casting any reflection upon Mr. Blackwell's Report—an able and clear document, although, as we think unfortunately, its author contents himself with the enunciation of a dogmatic opinion only, as to the circumstances that produced the fracture, and has not sustained his view by any appeal to calculation.

The problem itself is a dynamic question of considerable complexity, as is pretty evident from the fact that, so far as our knowledge goes, not one of the many able colliery engineers of the North, no one indeed, has ever attempted to grapple with it, up to this date, when the accident itself is almost beginning to be forgotten.

But, first, let us set aside one or two of the popular views on the subject, as amongst those that, it may be pronounced with certainty, *could not possibly* account for the fracture. First, it cannot have broken simply by statical overloading, long continued. A writer in the *Engineer* (Feb. 28, 1862) calculates the statical strength of the beam from the common formula—

$$\frac{(BD^2 - bd^2)\ 0{\cdot}25\ S \times 4{\cdot}5}{L} = W,$$

the breaking weight; and upon he data following—

B = 8 inches; D = 98 inches, the full length of the line of fracture;
b = 3·25 inches; d = 86 inches; and
L = 18 feet; S = 296 lbs. for a bar of cast iron 1 inch square;

and arrives at the conclusion that the ultimate breaking weight of the beam was = 976,707¼ lbs., or about 436 tons; and calculating the greatest dead load upon the beam at 64,641¼ lbs., or under 29 tons, and deducting 10 per cent. from the first value of W for defective casting (*i.e.*, the draw holes at the bosses), he points out that the statical load was no more than $\frac{1}{13{\cdot}5}$ of the breaking strain.

This is the smallest estimate that we have seen made in figures, of the passive strength of the beam, and it undoubtedly underrated both the breaking weight and the load.

A more trustworthy calculation was given by Mr. Atkinson, Government Inspector of Mines, in Vol. XI. of the "Transactions of the Northern Mining Institute."

From the formula—

$$\frac{500 \times BD^2}{L} = W;$$

and upon the data that the statical breaking weight of a bar of sound cast iron 1 in. square, and 1 ft. long, *encastre* at one end, and loaded at the other, is = 506 lbs. reduced to 500, as the beam was unsound at the bosses; and taking *mean* values for B and D, the line of fracture being 8 ft. 2 in. deep, he calculates the value of

W = 1,413 tons 8 cwt. 3 qrs. 18 lbs.

But the statical load, or "greatest steady strain," he says, did not exceed 106 tons 8 cwt. 3 qrs. 1 lb., acting at 18 ft. from the line of fracture, from which it follows that the greatest load was only about $\frac{1}{13{\cdot}25}$, the ultimate strength. The two ratios' though on independent and different data, closely coincide.

Now, as it is perfectly well known that, even under impulsive strains, cast iron may be exposed to forces producing more than one-fifth its ultimate extension, and remain for decades of years uninjured, there can be no hesitation in pronouncing that it is physically impossible that the Hartley beam was broken by the long-continued action of its steady load, even making every estimate of allowance for the variable nature and alteration of that load.

In what follows, we shall find that Professor Haughton has examined the question arising out of one of the other suppositions as to cause—namely, the possible strain that might have been visited upon the beam by the fall it got from off the screw-jacks.

That view alone *looked* feasible, because it was beyond the reach of the judgment we form by tactile experience of such things; no one could, by any analogy of experience, imagine what might be the stress upon such a mass of 42 tons, dropping upon two points at its mid length, from even a few inches in height.

Let us come, then, to what we may call the authorized version of the conditions that produced fracture. After describing the engine, the beam, and the loads which he calculated were upon it, Mr. Blackwell states:—"It appeared from the evidence of the men being wound up in the shaft at the time of the accident, that *a breakage of the spears in the shaft, by which the engine lost its load wholly or in part*, did occur prior to the breakage of the beam and the fall of its broken half into the pit;" "and that when this breakage of the spears did occur, the engine was commencing its inside stroke." Report, p. 32.

He proceeds:—"The resistance to the descent of the piston in the steam cylinder being thus removed, the piston would be carried downwards by the pressure of the steam on its upper surface, augmented by the vacuum below, amounting to a force of about 62 tons, and would rapidly acquire momentum in its descent through a stroke of 10 ft. in length, until both the piston and that end of the beam connected to it were suddenly arrested by the iron catch-pin, fixed upon the beam at that point, coming down upon the spring beams, where they were rendered perfectly rigid in their resistance by vertical cast iron columns beneath them."

"The engine beam was of iron of *fair quality*." "It was of the full ordinary sectional dimensions of beams used in engines of similar power." "The over-wedging of the beam centre *may have contributed* to render it *more liable* to fracture," but is "not alone sufficient to account for the fracture."

"*The breakage of the beam must be attributed to the violent concussion to which it was subjected*, when it, together with the steam piston connected to it, were suddenly arrested, after descending through a stroke of 10 ft., with the velocity acquired under the pressure of the steam, by coming in contact with the beams beneath, after the counterbalancing load in the shaft was partially or wholy lost."—Report, p. 32.

Such, in clear language, is Mr. Blackwell's decision. We shall, without further preface, submit it to the calculus of Professor Haughton. In the present section of these "notes," we cannot do more than give the preliminary investigation made by that gentleman, upon data supplied by us, and not rigidly exact, and which he desires shall be received as no more than a first approximation to the problem of the Hartley beam. Upon more precise data, as to loads and dimensions, form of the beam itself, &c., since then obtained, Dr. Haughton is still engaged with the calculation; and we hope in a succeeding part to give fully his exact determination of the strain possible to be produced by the train of circumstances set forth by Mr. Blackwell. Meanwhile, the following calculations will show the methods employed, and indicate the probable result of the final investigation.

APPROXIMATE SOLUTION OF QUESTIONS RELATIVE TO THE FRACTURE OF THE HARTLEY BEAM, BY REV. SAMUEL HAUGHTON, F.T.C.D., F.R.S.

PROP. I.—PROBLEM.

A beam, of rhomboidal shape, is supported by an axis passing through its centre, and loaded with equal weights at its extremities; it is required to find the tension and compression to which its parts are exposed.

Let l denote half the total length of the beam,
Let d, its depth,
Let t, its thickness;
Let W denote the weight of the beam,
and P, the weight suspended at each extremity.

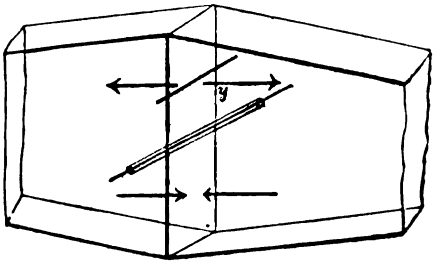
The *Moment of rupture* of the beam is equal to

$$\frac{(W + 6\,P)\,l}{6};$$

and the *Moment of resistance to rupture* is

$$t \int F y\,dy;$$

where F denotes the tension or compression per square inch at any distance y from the axis of the beam, in its central vertical section (*see* fig.). If C



denote the tension or compression per square inch at the top or bottom of this section, then (assuming for the present that the *neutral axis* passes through the centre of the beam), we have, by Leibnitz's principle,

$$F = C\,\frac{2\,y}{d}$$

therefore, equating the moments of rupture and resistance, we have

$$\frac{(W + 6\,P)\,l}{6} = \frac{2\,t\,C}{d}\int y^2\,d\,y = \frac{2\,t\,C}{d}\cdot\frac{y^3}{3} + \text{Const}\ldots(1)$$

This integral must be taken for the extended portion of the section, from $y = +\frac{d}{2}$ to $y = 0$; and for the compressed portion from $y = -\frac{d}{2}$ to $y = 0$; or, since both extension and compression are employed in resisting rupture, from $y = +\frac{d}{2}$ to $y = -\frac{d}{2}$;

therefore

$$\frac{(W + 6\,P)\,l}{6} = \frac{C\,S\,d}{6}$$

or

$$(W + 6\,P)\,l = C\,S\,d \ \ldots\ldots\ldots\ldots\ldots(2)$$

where $S = t\ d$ = the cross sectional area of the central vertical section of the beam.

herefore, finally,

$$C = \frac{(W + 6\,P)\,l}{S\,d} \ \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(3)$$

Example 1. If the beam be 34 ft. long, 8 ft. deep, and $9\frac{1}{2}$ in. thick, weighing 42 tons, and be loaded with 300 tons at each end, find the strain on each square inch of the top of the vertical central section—

$$C = \frac{(42 + 1{,}800)\ 17}{912 \times 8} = 4{\cdot}292 \text{ tons per square inch.}$$

Example 2. If the beam be unloaded, find the strain per square inch—

$$C = \frac{42 \times 17}{912 \times 8} = \frac{1}{10{\cdot}2}\text{th of a ton per square inch.}$$

Example 3. If the maximum strain that cast iron will bear, if *suddenly* applied, be 2 tons per square inch, calculate the forces, P, suddenly applied downwards to the extremities of the beam, that will just fracture its upper surface in the central section. In equation (2), write $C = 2$, and solve for P.

$$(42 + 6\ P)\ 17 = 2 \times 912 \times 8$$
$$714 + 102\ \ P = 14{,}592$$
$$P = 136 \text{ tons.}$$

—*Practical Mechanics' Journal.*

ON STEERING STEAM AND OTHER VESSELS.

By Commander F. P. Warren, R.N.

It is undeniable that the great length of modern ships (combined with the daily increasing necessity for rapid manœuvring), calls for some means of guiding their movements with greater ease and certainty than those afforded by the ordinary stern-rudder.

Reasoning by analogy, it is also evident that the attempt to control the movements of these lengthy vessels from one end alone, is wrong in principle, as shown by the manner in which nature effects a similar object. In doing this, however, we must not take aquatic birds as our example, as in their case the body is comparatively short, and is, moreover, provided with *two* propellers of considerable length, and so situated as to enable the creature, by working either one or both, as required, to regulate and control its movements with the greatest ease and certainty. It will, therefore, evidently be more correct to compare modern vessels with certain species of long-bodied fish. These, it is true, have their principal means of steering, namely, the tail, situated in a position somewhat similar to that of the stern rudder in ships; but here it will be found that the similarity ends, inasmuch as the body of the fish is flexible, and capable of accommodating its curves to the directions in which the creature desires to move, while that of the ship is entirely rigid, and incapable of any change of form tending to assist the action of the rudder.

It is evident (from the numerous and insurmountable practical difficulties such a construction would involve) that we cannot for a moment entertain the idea of making the body of a vessel capable of curvilinear movements, similar to those of a fish. But although such is the case, there is nothing to prevent the employment of a rudder at the forward as well as the after end, thus to some extent approximating to the perfection of nature, and giving a facility of control entirely unattainable where the ordinary stern-rudder only is employed. By this means, it is obvious that the vessel will be caused, in turning, to describe a circle of very much smaller diameter than if a single stern-rudder only were employed.

A well-known cause of difficulty in steering screw-steamers, arises from the action of the screw, which, by breaking the current of water, prevents its acting as in sailing-vessels directly upon the rudder. The water thus churned and broken by the action of the screw, loses much of its density, or power of resistance as a steering medium, and is hence greatly reduced in effectiveness. If this is attempted to be overcome simply by an increase of the area of the stern-rudder, it at once becomes necessary to make use of more powerful and complex machinery for actuating it, thereby involving increased liability to strain the stern-post, endangering the rudder-head, weakening the rudder itself, and consequently threatening danger to the ship, and to the lives of those on board.

In the plan now proposed, a safe auxiliary to the rudder astern, is placed in the dead wood of the bow—an arrangement which the fine line of present vessels, both war and mercantile, renders very easy of adoption; the aperture to receive the bow-rudder being formed abaft the stem, in the same manner as one is now constructed in the dead wood at the stern for the purpose of receiving the screw.

It is scarcely necessary to ... out the advantage of having two rudders ... ndent of each other, and not liable to be damaged at one and the same time by the same causes of accident; the bow-rudder being merely for use in narrow waters, and on occasions of difficulty and emergency, such as steering through a narrow and tortuous channel—coming suddenly upon a reef or strand—or in thick weather, upon a vessel, which the present rudder alone would not have sufficient stopping or turning power to avoid.

A reference to the inquiries into the loss of steamers, carried out under the direction of the Board of Trade, will show how numerous are the cases of vessels being stranded, owing to the length of time lost in coming round after the danger was seen. In such cases, the additional steering power, and facility of turning or backing off, afforded by the extra rudder would be of vital importance, and would prove the salvation annually of many of our mercantile steamers, and hundreds of lives.

In a gale of wind, when a steamer can but just head the sea, the stern-rudder would be greatly eased by the bow-rudder's acting to keep the ship's head up, thus enabling an easy helm to be carried, instead of the stern-rudder being jammed hard up to its great danger, and that of the ship. The case of the "Great Eastern" is one in point, and by her narrow escape from foundering when falling off from the sea after the accident to her *only* rudder, convincingly proves the necessity for an auxiliary, to which recourse can be had either for assisting the main rudder under peculiar circumstances, or for acting alone, when it, the main rudder, is disabled.

In cases of vessels striking the ground, the stern-rudder is frequently lost, and generally damaged; and, in consequence, merchant vessels which, under these circumstances, escape total loss, are obliged to go into port, requiring extensive repairs, and causing serious, if not ruinous, loss by delay, to owners, shippers, and consignees, which, in the case of a vessel fitted with an auxiliary rudder, would be avoided by the vessel being enabled to make a safe passage without incurring the disastrous loss of time, &c., referred to.

The advantage also of having a vessel under perfect command while going astern, can scarcely be overrated. At present a screw-vessel under such circumstances, is unmanageable; but, fitted with an auxiliary rudder, the largest vessel of this class would be able to leave its port or harbour without having to swing or wait for a tide.

Steam-tugs, so fitted, could, while under sternway, place themselves under the bows of a vessel with perfect safety and certainty.

To men-of-war it is undeniable, that an auxiliary rudder, entirely protected from shot, must be a great advantage in action: besides which it is to be borne in mind, that vessels of a large draught of water, as now fitted, invariably steer much worse in shallow than in deep water, and are, therefore, least manageable at the very time when their immediate answering to the helm is of the most vital importance, as when going into harbour, attacking shore fortifications, &c. The following extract from the "Transactions of the Institution of Naval Architects," page 139, vol. i., is the opinion of Rear-Admiral George Elliot, Assoc. I.N.A.:—"I believe that if a war broke out to-morrow, the commander of the fleet would call out all the paddle-steamers as auxiliary vessels; they are serviceable in action in a manner that screws cannot be. *The screws cannot back astern effectively, and cannot run under the bows and take a vessel in tow with the facility of a paddle-wheel.* I therefore think before the paddle-wheel steamer is condemned altogether, as has been the case, one word should be spoken in her favour for war purposes."

The auxiliary rudder, as explained, enables a screw-steamer to carry out in a perfect manner the manœuvres which an officer of Admiral Elliot's experience puts forward as a sufficient reason for pausing ere doing away with a class of vessels which, in other respects, is obviously far inferior to the screw for war purposes, and would only at best be retained for possessing qualities which it has been shown may be readily and simply given to the screw.

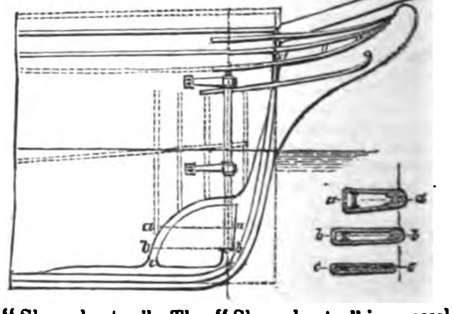
1. If the bow and stern rudders be considered as levers of the first order, the bow-rudder would have the same power to pivot or turn the vessel as the stern-rudder, if the areas be the same and the centre of displacement equidistant from each, the form of the vessel at either end being identical. The only vessel which we have in our service where an attempt has been made to fit her with a bow-rudder, is the "Weser," built by Mr. Scott Russell for the Prussian Government, and which was exchanged, together with the "Recruit," in 1853 or the beginning of 1854, for one of our frigates. An officer commanding the "Recruit," says:—"The bow-rudder was useful in the 'Recruit.' She has often gone out of harbour one end first and come back the opposite way for convevenience in taking in moorings. In harbours, and in the river Danube, it has often been used successfully to prevent the necessity of turning. I could not use it with success in starting from an anchor, or in conjunction with the after-rudder for turning purposes."

I may here observe, that, during the last Chinese war, the French gun-boats in the Peiho were fitted with bow-rudders; but they were of the same description as the stern-rudders. I have obtained the opinions of officers who were out there; but every one of them gives me an opinion, so far as I can judge, according to what he thinks the rudders did, for nobody can tell me distinctly how they really acted. No doubt they had full command over the vessel in going astern; but if the bow-rudder in the "Recruit," of which we have perfect data, had no power when going ahead, I cannot see how the French gun-boats could go ahead under command with their bow-rudder. They are fitted on exactly the same principle. They have a spindle outside the stern, and it is the same rudder as that in the "Recruit."

I now come to the trials which have been made with the "Princess Royal," and which, I may safely say, will establish the practicability of this rudder, or the Government would not have adopted it in the "Sharpshooter." The "Princess Royal" is one of the Ryde boats, a vessel of about 110 tons. She was the only vessel I could get, the manager of the company having kindly allowed the experiment to be tried in her, she being ready for launching from the slip. There was only forty-eight hours to fit her. So that instead of having the rudder placed as I should wish to place it, in the dead wood, as in the "Sharpshooter," which would have involved a good deal of work, I had the keel lengthened and an additional stem put on. The areas of the bow-rudder to stern-rudder were as 9 ft. to 15 ft. I may here mention, as is well known, that in a paddle-steamer when she begins to go ahead, the tendency is to draw down by the stern; so that the stern-rudder as fitted in that vessel became more immersed the faster she went, while the bow-rudder was proportionately lifted, losing power. Besides, the narrowness of the stem in this vessel, which I will point out when we get further into the question of fitting, produced a very great disadvantage on the action of the rudder.

I may as well point out that the difference between this and almost all other bow-rudders that have gone before it, is the manner in which it is hung. The spindle is in the after part in every other rudder. I believe there is a rudder that shifts on the stem, fitted in the same manner as mine; I have not seen it, but from the experiments I have tried, I cannot conceive that it has any active power in steering a vessel. Another is hung on or in an outer stem, but not in the dead wood as in the "Sharpshooter," which is the point where the power is gained, as the further aft in the vessel's bow the rudder can be placed, the greater the power.

My bow-rudder is entirely protected from shot. The drawing shows how it is fitted to the



"Sharpshooter." The "Sharpshooter" is a vessel with a light draught of water. If the rudder were fitted to the "Warrior," the men who steered the ship would be from 6 ft. to 8 ft. under water. And if the upper tiller were shot away, not only the rudder itself but the men who steered the ship by the lower wheel, would be completely protected from shot.

Another feature is, that the power of steering a ship when going astern is equal to the present rudder when steering a vessel when going ahead. I

take this from the report of Captain Coles:—The areas of the two rudders being as 9 ft. to 15 ft.; the stern-rudder going full speed, head to port, was 3 min. 9 sec.; going at half speed, 3 min. 10 sec. With the bow-rudder alone, at full speed, it was 5 min. 34 sec.; at half speed, it was 5 min. 17 sec. This, within a fraction, gives the exact ratio between 9 ft. and 15 ft.; that is to say, the area of 9 ft. bow to 15 ft. stern, is as 3 min. 9 sec. to 5 min. 34 sec. Going astern the circle was completed with the stern-rudder, at full speed, in 6 min. 56 sec.; at half speed, in 6 min. 11 sec. But here the bow-rudder has an immense gain, for at full speed the circle was completed in 4 min. 20 sec., and in 4 min. 20 sec., singularly enough, at half speed. We cannot arrive at any reason for this, but it is the simple fact that there was a difference of 45 sec. between full speed and half speed with the stern-rudder, and no difference at all with the bow.

At first sight, it would appear that when the ship is going astern, there is an enormous action exerted on the rudder to tear it off its spindle. Practice does not give that result. It has been tried repeatedly. In the "Princess Royal," it was only a temporary thing, and fastened with inch bolts; the gudgeon was one-eighth iron and a simple strap. On one of the trials when going astern, steered by the stern-rudder, at full speed, the rudder got across the ship's stern, and became unmanageable, and the tiller was bent double in trying to right the helm; while on going astern full speed with the bow-rudder, and the rudder being let go hard over, it was righted again by one man; the length of both tillers were the same. One man was able to right the bow-rudder, while three men broke the tiller of the stern-rudder in trying to right it. This, I think, can be accounted for by supposing that the current of water which passes through the aperture, when the rudder is put over, takes away that apparent resistance which we find with the stern-rudder, when we bring the rudder over at a certain angle, we bring it over against a fixed body, and we are piling the water up against it; in the other case we do not bring it up against any fixed body, we only have the resistance of the water itself.

The next point is the very small area in making the circle when both bow and stern rudders are worked together. There were two trials under the superintendence of Captain Coles, and two trials under Captain Broadhead; and at both these trials there was, as near as one can judge without measurement, a reduction of 50 per cent. in describing the circle when both rudders were used in conjunction. The gain of time was small; at the best it was not more than 14 sec., but the area was reduced 50 per cent. Where we wish to stop a vessel suddenly, there would be great advantages in two rudders, because we would put the bow-rudder over one way, and the stern-rudder over the other, and we would have a stopping power at once, the one rudder balancing the other.

I shall now refer to Captain Broadhead's report of the trial in the "Princess Royal." In this vessel, from some cause or other, which we only found out after she was docked, a difficulty was experienced in making her complete the circle to starboard. It arose from the crookedness of the keel, which had been put on out of the straight, so that she carried, under ordinary circumstances, a strong port helm, and she could not be got round in one way for some time; but at the trial by Captain Coles, and by humouring her, the circle was completed to starboard; that being done, it satisfactorily proved that the rudder acted perfectly, but the fault in steering arose from the malformation of the vessel. This was the opinion of the Government officers.

Trials of Commander Warren's Plan of Steering.
24th July, 1862.

SIR,—In pursuance of instructions communicated in your memoranda of the 19th inst., to witness Commander Warren's plan of steering with a bow-rudder, as fitted to the "Princess Royal," Ryde packet, we have to report that we yesterday made the following trials, but must first observe that the vessel is ill-adapted for the purpose, as from some unexplained cause, probably a bend in the keel, the stem not being perfectly upright, or malformation in the bottom, while the bow-rudder acts readily in turning to port, it is nearly useless in turning to starboard.

1st Trial.—In Harbour.—Proceeded from off dock-yard at full speed, through the ships to the entrance of Fareham Lake, above Hardway, where the vessel was turned and taken to Spithead. Throughout the distance she was steered with the bow-rudder, except when making the turn up the harbour, and when avoiding objects on the port side, when it was found the port helm had no effect.

	min.	sec.
2nd Trial.—At Spithead.—With stern-rudder, helm hard astarboard, vessel made circle in	3	13
With bow-rudder placed as above, vessel made circle in	7	9
Gain of stern-rudder over bow	3	56
3rd Trial.—With stern-rudder, helm hard aport, vessel turned in	3	45

With bow-rudder placed as above, vessel only turned 8 points in 7 minutes, and would have gone on shore before turning. The attempt to turn her was therefore given up.

	min.	sec.
4th Trial.—Vessel was stopped dead. The helm of bow-rudder was put hard astarboard, vessel made circle in	6	54
5th Trial.—With both rudders, vessel made circle to port in	2	51

The small circle in which the vessel was turned was very remarkable.

	min.	sec.
6th Trial.—Vessel going astern at full speed, made the circle with after-rudder, helm hard astarboard, in	7	29
Under similar circumstances, with bow-rudder, in	8	27
Gain of stern over bow rudder	0	58
7th Trial.—Vessel going astern at full speed, helms of both rudders hard aport, vessel made circle in	5	0
Or a gain of stern-rudder only of	2	29

To conclude the trials, the after-rudder was locked when about a mile distant from Ryde Pier, the vessel put at full speed, and the bow-rudder only used, when she steered stern foremost in the most perfect manner, passing through the ships at Spithead up the harbour past the dockyard, when she was turned without the stern-rudder being touched.

The comparative areas of the bow with the stern rudder is as 9 to 24.

From what we have observed, we think the bow-rudder to possess about half the power of the after one when steering ahead, which would doubtless be increased were the area of the two rudders more nearly equalized, to give a fair estimate of its power.

In conclusion, it appears to us that the invention is of value, but think it capable of great improvement in its details.

We return herewith Commander Warren's model and papers, and have, &c.,

(Signed) H. BROADHEAD, Captain in charge of Reserve.
I. TONKIN, Master Attendant.
H. CRADOCK, Master Shipwright.

I have no doubt many know what nice steerage it requires threading the way amongst the ships in ordinary of Portsmouth Harbour.

Turning now to the subject of vibration. Up to this time I have only spoken of the rudder as an auxiliary rudder. But I have hopes that this rudder will be able to be used as a main rudder at sea, and this would lessen the vibration of the screw, which we know increases, in a very great degree, directly the helm is put over, and piles the water against the screw. If we steer by the bow-rudder we do away with the increased vibration caused by steering with the after-rudder. Scarcely a month passes that we do not see some of our finest ships returning to port to repair leaks in the stern-post caused by the vibration of the screw.

In conclusion I will deal with the application of the bow-rudder in sailing vessels. So fitted, a sailing vessel has two chances of staying instead of one. If we put the helm down, the vessel comes up head to wind, and then gathers stern-way; we shift the helm and square the yards, and with the stern-way she comes round and answers her helm. It is impossible for a vessel to miss stays, for she can go round as certainly going astern as when she is going ahead.

CASTING HEAVY GUNS.

THE principle involved in the construction of ordnance on the Rodman system, is simply that of cooling the core round which the metal is poured by passing a current of cold water through it; thus equalizing the contraction, and adding enormously to the strength of the gun. The system has not as yet been adopted in this country, and therefore the following, for which we are indebted to the *Pittsburgh Dispatch*, is not devoid of interest:—We have already noticed the fact that preparations were progressing at the Fort Pitt Works, in this city, for the manufacture of 20-in. guns, the lathe, patterns, &c., being in an advanced condition. As the experiment of manufacturing a gun of such a calibre, however, is one of great risk, it was determined to settle at least one point practically before attempting to mould the great gun, by melting at a single heat, nearly the same quantity of metal as would be required for the 20-in. For this purpose, two guns were moulded of the 15-inch navy pattern, and each furnished with a 12-in. instead of a 15-in., hollow core, making the round weight of each of the guns nearly as great as the columbiad 15-in. These moulds were placed side by side in the pits of the new foundry, and five of the furnaces in the foundry were charged—three for the special purpose of casting great guns, and two for the ordinary work of the shop. The respective weights of these charges will give some idea of the capacity of these enormous furnaces, being 34, 19, 19, 13, and 18½ tons—an aggregate of nearly 94 tons. 72 tons of this metal, being the charge of the three large furnaces, were designed for the casting of the experimental guns. The metal was led from each of these furnaces to a large pool, equidistant from each of the moulds, and communicating by two "runners" with the two "gates" of each.

About mid-day, the three furnaces were tapped in quick succession, and in a moment three streams of molten iron were pouring into the pool, from which, as the metal rose to the level of the openings, two fiery lines shot into each of the moulds. Notwithstanding the unusually risky character of the experiment everything passed off successfully, and the streams of hot metal and cold water, crossing and interlacing on their way, poured into the moulds without accident.

MANUFACTURE OF BOOTS AND SHOES BY MACHINERY.

THE old system of making boots and shoes entirely by hand labour will soon, to all appearance, be numbered with the relics of a past age. The war having created an immense demand for boots and shoes, hand labour was found unequal to the task of supplying it; but necessity—well-named "the mother of invention"—soon provided a remedy. Machines have been constructed and are now in use executing the different operations necessary to the manufacture of such articles, and with a rapidity and accuracy of action which far excel the efforts of hand labour. A manufactory in which boots and shoes are made upon an extensive scale, by machinery, has been recently established in New York and is thus described by the *Scientific American*:—

Three large apartments are occupied by the operatives, mechanism, and goods. The skins for the uppers are first spread out, examined, and selected according to the purposes for which they are required. Different cutters then cut out the respective parts according to the size and form required, and these are all arranged and classified. After this, these separate parts are given out in lots to be sewed by machines, and those uppers which are intended for boots are crimped, and the whole made ready for receiving the soles. The more heavy operations of punching, sewing, pegging the soles, and finishing the articles are next executed. The sole leather, in hides, is first steeped in a tank of water to soften it; then it is thoroughly dripped, and afterwards cut by a machine into measured lengths of a certain breadth, according to the size of the sole wanted. After having become sufficiently dry, these cut strips of leather are run between rollers, and also submitted to severe pressure under plates in a press, so as to effect as complete a compression of the fibres as is attained according to the old mode by beating with a hammer upon a lapstone. From these compressed strips, soles of the different sizes are punched out at a single blow by a machine, the cutter of which is of the size and form required, and it turns round so as to cut a right and left sole alternately. Heel-pieces are also cut out by hollow punches at a single blow. The edges of the soles and heels are next smoothed and polished in a small rotating machine; and another machine then makes the channels in the soles for the rows of stitching. After this, the under soles and uppers are fitted upon lasts and made ready for sewing. This operation is executed by Mackay's peculiar machine, adapted for this specific purpose. The waxed thread is wound upon a vertical spool, and is conducted through a guide situated on the top of an elbow secured on a swivel joint capable of turning under the needle, and conducting the thread into the crease around the sole. The needle operates vertically above the sole, and the waxed thread is fed into the interior of the boot or shoe

by the guide, the needle descending through the sole, drawing through the thread and forming the stitches, which are pressed down close into the crease by a tracer-foot, upon which great pressure is exerted. In this manner the sole and upper are united firmly and neatly together in a few seconds, without employing a welt. Hand-sewing cannot be compared with such machine-work for accuracy and rapidity. Another machine is employed for putting on double soles with copper pegs. A thin strip of copper is fed in at one side and the holes are punched in the sole, the pegs cut and put into the holes, and then driven down at one continuous operation, with a speed corresponding to that of sewing the soles. The crossing of the half sole at the instep is pegged, and also fastened with a screw at each side by hand; the heels are also pegged down. The edges of the heels are neatly trimmed by a small rotating machine, and the soles are also rubbed down by a machine; so that nearly all the operations connected with the manufacture of boots and shoes in this establishment, are performed by machines designed especially for the purpose. The legs of the boots are stretched and the wrinkles removed by new boot-trees secured to benches and are expanded in an instant from the interior by pressing on a treadle with the foot. These boot-trees are altogether superior to the clumsy old wedge kind. The materials used in the manufacture of these articles appear to be of a superior quality, the machines not being adapted for operating on inferior patch leather. Another novel feature connected with these machines is that they are driven by one of Roper's hot-air engines, illustrated on page 97, Vol. VIII. (new series) of the *Scientific American*. It has been running for several months, requiring but little attention and consuming a very small quantity of fuel. The accurate operations of these machines and the rapidity of their action place them in a highly advantageous position for manufacturing boots and shoes. The price of hand labour had become so high, and workmen so scarce, that such machines became a necessity, and the change effected by their use is equal to four times the quantity of work executed by hand labour —that is, one hundred men will turn out with these machines as much work as four hundred men without them. The saving of labour to the country is therefore immense. About 500 pairs can be turned out daily in this establishment. Perhaps no labour connected with boot-making is so severe as that bestowed upon burnishing the heel with a warm iron. This work is still executed by hand, but a machine is now being set up to accomplish this finishing operation, and it will soon be at work. For centuries no improvement seems to have been made upon the old system of boot and shoe making; when, all at once, as it were—within the space of two short years—the whole art has been revolutionized.

TO CORRESPONDENTS.

The MECHANICS' MAGAZINE is sent post-free to subscribers of £1 1s. 8d. yearly, or 10s. 10d. half-yearly, payable in advance. Post-office orders made payable to Mr R. A. Brooman, of 166, Fleet-street, E.C.

Advertisements are inserted in the MECHANICS' MAGAZINE at the rate of 6d. per line, or 5½d. per line for 6 insertions, 5d. per line for 13 insertions, 4½d. for 26 insertions, and 4d. a line for 52 insertions. Each line consists of about 10 words. Woodcuts are charged at the same rate as type. Special arrangements made for large advertisements.

All communications should be addressed to the EDITOR, 166, Fleet-street.

To insure insertion in the following number, advertisements should reach the office not later than 5 o'clock on Thursday evening.

RECEIVED.—L. T., Col. G., C. W. W., J. W. G., H. J., L. T., G. S., L. D., J. H., J. N., R. P. E.

FAN (Birmingham).—By making the shape of the blades elliptical, you can reduce the noise. The improved French fans have a central disc instead of spokes.

IGNORANCE.—We doubt that any advantage would be derived from working dock capstans by steam power, except in exceptional cases. We do not see very clearly how a screw-jack could be worked in confined situations by a hand wheel.

C. Y. (Manchester).—We cannot say.

D. V.—Why not use india-rubber valves? They will work without noise and last a very long time.

Correspondence.

ENGINEERING SOCIETY.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

SIR,—A society has been formed at King's College amongst the students of the Engineering Section, to promote the advancement of a knowledge of this profession by the reading [illegible] and open discussions. Its meetings ar[illegible] 2.15 to 3.30 p.m., on Thursday after[illegible]

Knowing well the interest you always take in all matters that are likely to advance engineering science, I take the liberty to ask you to insert this note in your valuable paper, to the effect that the society will be happy to see any gentlemen from engineering offices who may wish to attend its meetings. A card of admission can be obtained on application to the President.

I am, Sir, yours &c.,
P. MAITLAND,
President for the October Term.

THE RECENT GUNNERY EXPERIMENTS.

SIR,—I beg to forward to you an *authentic* table of the results obtained at Shoeburyness, on Friday last, with my 9-inch gun. These results would have been very much better, had it not been for an accident—namely, that the zinc bearings upon the shot were put on in so inefficient a manner that they were partly or entirely blown off in the gun, thus causing an unusual play of the shot in the bore and affecting their flight considerably. This accident—which the *Times* reporter omitted to mention—cannot occur again. Considering the conditions under which the gun was fixed, the results were much better than could have been expected; the difference in the firing—both as regards range and accuracy—between my gun and the 100-pounder Armstrong gun, being about the same as that which exists between the 100-pounder Armstrong gun and the 12-pounder Armstrong field-piece.

The fact that this 9-inch gun is the first which has stood even thirty-three rounds with a charge in proportion to its calibre, was overlooked by the *Times* reporter. His remarks respecting the cartridges, &c., displayed so complete an ignorance of the subject, that it would be quite a waste of time to do more than give them this notice.

I am, Sir, yours, &c.,
LYNALL THOMAS.

Southend, Nov. 24, 1863.

DRAWING PENS.

DEAR SIR,—I cannot think that I am the first who has remarked the following, but now beg of you to make it public, that we may, in a few years, get rid of the nuisance of having so universal an instrument as the drawing-pen incorrectly constructed.

The essence of an even line is that, in inking there should be no change of distance between the two ruling nibs; but to make a line true to the guiding edge, there must be a moderate amount of pressure on that edge. Very few pens have this idea predominant in their construction; there should be extra stiffness in one or both the nibs. The extreme bulging and "lengthy" forms of these are quite unnecessary and ugly, and the hinged ones, often, a little gained and much lost. Let the inner nib (in ruling) be, say, twice as stout as usual; the outer one half as stout again especially flatwise; the screw twice as large in its head, for finer adjustment; and its shank stout enough to withstand the extra strain, and "inking in" will become a pleasure, and the pen-maker will win for himself a thousand blessings.

Having observed this, and experimented upon it for more than ten years, I add with confidence, "Believe those who have tried."

I am, dear Sir, yours truly,
HERBERT HURST.

Meetings for the Week.

MON.—*British Architects*, at 8 p.m.
Medical Soc., Lettsomian Lecture, at 8.30 p.m.
London Inst., "On English Costumes from the Anglo-Saxon Period," by Rev. Henry Christmas, F.R.S., at 7 p.m.

TUES.—*Inst. Civil Engineers*, 1, Renewed Discussion on "Cornish Pumping Engines." 2, "Lambeth Bridge," by P. W. Barlow, Esq., at 8 p.m.

WED.—*Geological Soc.*, 1, "On the Correlation of the Pliocene Deposits of Belgium, Germany, and Southern England," by Herr A. von Koenen. 2, "On the Liassic Strata of the Neighbourhood of Belfast," by R. Tate, Esq. 3, "On Palæozoic Strata in the Vicinity of the Bosphorous," by W. R. Swan, Esq., at 8 p.m.

THUR.—*Antiquaries*, at 8 p.m.
Linnean, at 8 p.m.
London Inst., "On the Principles and Applications of Organic Chemistry," by J. A. Wanklyn, Esq., at 7 p.m.

FRI.—*Architectural Assoc.*, Class of Design—Open Timber Roof.

SAT.—*Association of Foremen Engineers*, "A New Slide Link Motion," by Mr. Stanley, at 8 p.m.

Miscellanea.

Messrs. Childs and Co., of Alleghany, Pa., have been experimenting with flax batting as a substitute for cotton, and have succeeded in producing an article which is pronounced excellent.

The *Commercial Bulletin*, Boston, states that the Putnam Machine Company, of Fitchburg, Massachusetts, have contracted for the manufacture of the heavy guns for the coast defence of the State, and are erecting buildings and machinery. A portion of the guns will be of the Blakeley pattern, weighing from 20 to 30 tons each, and all of them will be rifled, and are designed to throw a projectile weighing from 300 to 600 lbs.

It is with the deepest regret that we state that Captain Shaw, the chief of the London fire brigade, still remains in a very critical state. Our readers are, doubtless, aware that he met with the deplorable accident, from the effects of which he now suffers so acutely, while in that active discharge of his duty for which he is so well known. Many distinguished personages have called at Watling-street Station, and Her Majesty has also sent to ascertain the state of the gallant Captain.

Pneumatic tubes are being laid down between the central telegraph office, the Exchange, the railway stations, and several other buildings of commercial and political—or rather police importance—at Berlin. There will be two steam engines attached to every tube, the one condensing and the other rarefying at either end.

The following letter has been addressed by M. Chevalier, the eminent French political economist, to Mr. R. A. Mactie, of Liverpool, on the subject of the patent laws:—Lodeve (Herault), November 16, 1863.—My dear Sir,—You have made me communications of interest relating to patents for inventions. The patent system, as constituted in all countries where it is established, is a monopoly—an outrage on liberty and industry. It has consequences that are disastrous, seeing there are cases where it may stop business operations for exportation and even for home consumption, because it places manufacturers who work in a country were patents are established at a great disadvantage in competing with others who live in States, such as Switzerland, where patents are interdicted by law. Pratice, experience, which is the supreme authority in the world shows daily, in France particularly, that the system is a scourge on industry. What might be substituted is a system of recompenses, either national or European, as you have proposed, to be awarded when practical use has pronounced on the merit of each invention, and when the originality shall admit of being established. All the friends of industrial and social progress ought to unite their efforts to liberate industry from the shackles that have been bequeathed from the past. That of patents is one of those which there will be most urgency to get rid of.—Believe me, MICHEL CHEVALIER.

Rear-Admiral F. Bullock has been making a series of experimental trials on board the paddle-wheel steamer "Vivid," Commander W. H. Allen, which

has been placed at his disposal by the Admiralty, at the measured mile, Maplin Sands, near Chatham, for the purpose of enabling him to form correct tables and lay down a code of rules and regulations for the use of his newly-invented permanent ship-log, which is about to be introduced into the service. The Lords of the Admiralty are so well satisfied of the importance of the invention, that orders have been received at Chatham for the new log to be fitted on board the "Liverpool," 39, 600-horse power, Captain R. Lambert, belonging to the Channel squadron; and also the paddle-wheel steamer "Geyser," 6, 280-horse power, Commander M. R. Pechell.

Lately, a small paddle-boat has been plying on the Humber at a rapid rate. We understand it is worked by the pendulum, instead of oars, and it is the invention of a gentleman who is well known in London and Hull for his numerous inventions. It is also applicable to drive carriages on the high roads, and if constructed for the rail would go at the rate of 20 miles the hour. A carriage holding two gentlemen has several times been driving about Hull, then working its way to Beverley, and over the Ferriby Hills. It is the intention of the patentee to propel ships and life-boats by the pendulum, which may be applied to either screw or paddle. The apparatus is fixed in the boat, and is ready for use at any moment. In case of emergency this system must be of admirable service. The boat, which is a ship's jolly-boat, was tried from Hull to Paull, with four workers, and ran the distance in 27 minutes. The same distance a six-oared race-boat takes at least 25 minutes, the men pulling at the top of their strength. Whilst in the pendulum boat not a coat was taken off. Were the apparatus transferred from the jolly-boat to the race-boat, the inventor asserts that the same distance would be run in 15 minutes. The pendulum boat can be worked with half the ease of an oared boat, and any one unaccustomed to pulling can work the pendulum in two minutes, and continue to do so for 20 or 30 miles without fatigue. Any common boat can be fitted with the apparatus. The York papers state that the inventor intends making further experiments on or about the 23rd inst. on the Humber.

An ingenious Frenchman has discovered a most economical way of lighting cities, and proposes to apply it to Paris. Balloons, from the cars of which are to emanate an electric light, are to be fixed at certain stations, and hover over the city, at the proportion of one balloon to 80,000 persons; the city would be lighter at night than it often is in winter by day.

Experiments are being made in France with a new kind of rocket, which is to prevent the enemy from working at night. Besides giving a most brilliant light, illuminating a distance of 200 metres when let off, it offers the additional advantage of finally bursting like a howitzer, and carrying wholesale destruction into the hostile camp.

A scientific expedition, led by the eminent north country naturalist, the Rev. H. B. Tristram, of Greatham, is on his way to Syria. The members will employ themselves several months in exploring the zoology, botany, and geology of that interesting land.

The trial of Mr. Lynall Thomas's 9-in. muzzle-loading gun, carrying a 300-lb. shot, took place at Shoeburyness on Friday. The results were somewhat unsatisfactory. Ten rounds were fired, and the result is that at 2 deg. elevation the difference in the range is 164 yards; at 5 deg., 278 yards; and at 10 deg., 437 yards—all large numbers compared with those obtained in experiments with other rifled guns at similar elevations. The difference in the velocities is also large, being 142 ft. per second. It is just, however, to state that Mr. Thomas ascribes these results to the excessive length of the shot, and the finishing of the ribs too abruptly where they join the chamber of the gun, though *per contra* it is stated that the guns and shot have been manufactured under his own direction, and his objections should have been taken earlier. Mr. Thomas also complains that the powder was not rammed home, but it is stated that the difference of a few inches in the ramming home does not cause material deviations in other rifled guns, and that this is a defect in Mr. Thomas's.

The handsome new iron ship "Imperatrice Eugenie," built by Messrs. Scott and Co., Cartsdyke, for an Aberdeen firm, arrived at Natal on the 2nd ult., from London, in 58 days, and from the Land's End in 54 days—an almost unprecedented passage.

The French iron-clad squadron is expected at Cherbourg in about a week. It has experienced comparatively fine weather, and this time the members of the commission have not been prostrated by the *mal de mer*. The accounts that have reached us do not agree with those previously published by the *France*; the "Solferino," we understand, has come to grief, and will have to be towed home, having broken two blades of her screw. All the ships will require to be docked. If this be true, we leave our readers to decide whether these iron monsters can be considered good sea boats.

The many schemes of the day for the development of this, that, and the other, have caused some persons interested both for the district, and also of a patriotic disposition—though credit is not asked for the latter—to draw attention to the resources of Dartmoor. This place, it is said, has an area of 80,000 acres, and contains an almost inexhaustible supply of excellent granite, millions of tons of peat, and many thousand acres of good grass land. Tin is to be raised from almost all parts of the moor. The great want is a means of cheap locomotion by which the granite and peat, a valuable substitute for coal, may be transported to the surrounding districts. A great quantity of vegetables also could be raised there, as has been abundantly proved, and there would be formed a working population. Here is a chance for a dozen more new companies.

On Wednesday forenoon two large vessels built of steel were launched from the building-yard of Messrs. Jones, Queggan, and Co., at Liverpool. One was a sailing-ship named the "Formby," of 1,271 tons tonnage, built for the East India trade; the other a paddle-wheel steamer named the "Hope," of 1,492 tons. At a *dejeuner* which took place after the launch, Mr. Jones made some remarks on these vessels. He said that steel is much stronger than iron, weight for weight, and, consequently in shipbuilding, that equal strength can be given with less weight of steel than of iron. The strain resisted by iron-built ships had been found to be from 19 tons to 20 tons per square inch, while the resistance of steel is found to range from 42 tons to 48 tons, giving a mean of 45 tons for steel, or considerably more than double that of iron. Keeping these results in view, the "Formby," a vessel built of steel, required 500 tons of material in her hull, while a similar ship made of iron would have required 800 tons. The difference in weight of hull would cause a difference of nearly 2 ft. in displacement in favour of the steel vessel, requiring also less propelling power. In the case of steamers, the advantages were still more obviously in favour of steel. If the "Persia," a steamer of 3,600 tons and 900-horse power, had been built of steel instead of iron, her displacement would have been diminished about one-sixth, and she would have been enabled to carry double her present cargo. Mr. J. Reed, the Chief Constructor in the Royal Navy, who was present, said he should watch with great interest the career of the two ships which had just been launched. He remarked that merchant ships can be built to test a principle when war-ships cannot, as the former can be examined and repaired annually, while the latter are sent abroad for periods of three or four years. He perfectly agreed with what had been said of the importance of steel for the construction of small ships, and stated that the Government took great interest in the question of employing steel as a material for shipbuilding.

Patents for Inventions.

ABRIDGED SPECIFICATIONS OF PATENTS.

THE Abridged Specifications of Patents given below are classified, according to the subjects to which the respective inventions refer, in the following Table. By the system of classification adopted, the numerical and chronological order of the specifications is preserved, and combined with all the advantages of a division into classes. It should be understood that these abridgements are prepared exclusively for this Magazine from official copies supplied by the Government, and are therefore the property of the Proprietors of this Magazine. Other Papers are hereby warned not to produce them without an acknowledgement:—

BOILERS AND FURNACES, 966, 972, 1006.
BUILDINGS AND BUILDING MATERIALS, 1011, 1015.
CHEMISTRY AND PHOTOGRAPHY, 967, 1012.
CULTIVATION OF THE SOIL, including agricultural implements and machines, 962, 971, 976, 995, 1001.
ELECTRICAL APPARATUS, 963.
FIBROUS FABRICS, including machinery for treating fibres, pulp, paper, &c., 961, 965, 970 973, 980, 992, 996, 999, 1005, 1013.
FOOD AND BEVERAGES, including apparatus for preparing food for men and animals, 964.
FURNITURE AND APPAREL, including household utensils, time-keepers, jewellery, musical instruments, &c., 959, 1002, 1014, 1017.
GENERAL MACHINERY, 960, 974, 987, 989, 994, 997, 1016.
LIGHTING, HEATING, AND VENTILATING, 983.
METALS, including apparatus for their manufacture, 993, 1008.
MISCELLANEOUS, 968, 969, 977, 982, 985, 986, 988, 998, 1000, 1004, 1010.
ROADS AND VEHICLES, including railway plant and carriages, saddlery and harness, &c., 975, 984, 991, 1003, 1007, 1009.
SHIPS AND BOATS, including their fittings—*none*.
STEAM ENGINES, &c., 978, 979, 981, 990, 1018.
WARFARE, 958.

958. S. MOULTON. *Improvements in apparatus or means for lessening the recoil of cannon.* Dated April 16, 1863.

One part of this invention consists in the application of a break to the wheels or axle of the gun carriage. The particular construction of break which the patentee prefers to employ for this purpose, although he does not confine himself thereto, consists of a central shaft passing through the cheeks of the gun carriage, to which is attached a lever acting upon two clamps (or other form of friction surface) which clutch a drum or roller fixed to each axle of the carriage wheels, the pressure of the clamps being tempered by the action of india rubber or other suitable draw springs. Another part of the invention consists in attaching an elastic ring or rings of india rubber within an iron or other metal ring, by preference of oblong form, fixed to each end of the hawser of a ship's gun, at the parts where such hawser is fastened to the ship's side or deck, and to the side of the gun carriage. *Patent abandoned.*

959. W. OLDFIELD. *Improvements in the construction of locks, applicable for despatch and other boxes, writing and dressing cases, or other similar receptacles.* Dated April 16, 1863.

This invention consists in so constructing and arranging the parts of a lock that the lock and bolt may be applied to and carried by the upper part or cover of a despatch box, or of a writing or dressing case, or other similar receptacle, the key being introduced through a keyhole formed in the upper surface or lid of the box or case. The locking plate or catch is fixed on the lower portion of the box or case, by which arrangement despatch boxes, writing, dressing, or other folding-cases can be unlocked, and readily opened out without reversing their position after being unlocked, as is the case when the locks are applied to the lower portion of such articles. *Patent completed.*

960. A. SAMUELSON. *Improvements in the construction and arrangement of machinery and apparatus for the manufacture of oil.* Dated April 16, 1863.

This invention relates to a peculiar arrangement of machinery and apparatus for the manufacture of oil, and particularly intended for use in the colonies and in foreign countries, and consists in so arranging and disposing the various parts as that all the shafting required, in place of being attached to the building containing the mills, is attached to or forms part of an independent framing, forming part of the machinery itself, so that no separate fitting or attachment is required for such shafting, and the same is quite independent of the buildings, the advantages attained being that the fitting or fixing abroad by skilled workmen is dispensed with, and the whole of the machinery being compact is easy of export and removal. *Patent completed.*

961. T. A. W. CLARKE. *An improved construction of shuttle driver, and apparatus for working the same.* Dated April 16, 1863.

This invention relates to a novel arrangement of parts for effecting the driving of shuttles, the object being to ensure the proper action of the shuttle. The driver is a sliding rod provided with teeth or projections for taking hold of the shuttles, and traversing them to and fro through the shed. These teeth are so situated on the rod that, while the one that engages with the shuttle for traversing it in one direction is operating, the other is out of action, and clear of the bearings in which the driver slides. They are brought alternately into position for working the shuttles by the rocking of the driver in its bearings. Fitted to the extremity of the driver is a rack which gears into a pinion operated by a crank arrangement to be presently described, and by this means the to-and-fro motion is given to the driver. A pin projecting from the driver takes into the slot in a fixed plate, and by descending an incline in that slot transmits the axial motion to the driver. *Patent abandoned.*

962. F. A. E. G. DE MASSAS. *Improvements in smut machines, and in machines for cleansing and peeling grain and seeds.* Dated April 16, 1863.

In this improved machine a drum having a rough surface, and capable of rotary motion, is fitted within a slightly inclined fixed casing, having on its inner surface three sets of brushes of graduated strength or hardness; the first or hardest set consists of wires surrounded by or combined with bristles, each cluster of wires having a cluster or number of bristles round it; the next or softer set is of French whisks, or other fibre; and the third or softest set is of cocoa-nut fibre, or other fibre softer than the second set. Between the second and third set is a surface of wire gauze. The inventor mostly has this arrangement of brushes of wire gauze on the lower portion of the inner surface of the casing, while on the upper portion thereof is only a set of brushes of the first description (wire and bristle) combined with or having next to it a wire gauze surface. *Patent abandoned.*

963. R. KNIGHT. *Improvements in treating and preparing iron, copper, and other wires, for telegraphic and other uses, for the purpose of preserving them from corrosion or decay.* Dated April 17, 1863.

The patentee claims treating and preparing iron, copper, and other wires for telegraphic and other uses by coating such wires with pure tin, and condensing the same thereon by any suitable mechanical means, as described, for the purpose of compressing or condensing the c[illegible] f tin when applied on the surface of metallic wire [illegible]

completely close up the pores of the tin as to prevent the coated wire from being chemically acted upon by acid or other solutions, or from the oxygen of the atmosphere, or from other atmospheric, gaseous, aqueous, or submarine influences. *Patent completed.*

964. S. RILEY. *Improvements in the manufacture or preparation of cocoa and chocolate.* Dated April 17, 1863.

This invention consists in the application (as a compound for commercial purposes) of coffee, or its extract or essence, with cocoa, its essence or extract, or its husks, all or singular; also in the application of such combination or combinations with taraxacum, chicory, or calcined sugar, their essences or extracts, all or singular, which compound may be prepared by the mixing of coffee and cocoa, or the husks of cocoa, with taraxacum or chicory, or calcined sugar, in various proportions; or it may be prepared by the mixing various proportions of all the said articles. *Patent abandoned.*

965. J. RICHMOND, T. RICHMOND and D. HARLING. *Certain improvements in looms for weaving.* Dated April 17, 1863.

This invention consists in a novel arrangement and combination (which we cannot here describe in detail) of apparatus for regulating the tension and delivery of yarn from the warp beam during the process of weaving. *Patent abandoned.*

966. J. GOUCHER. *Improvements in steam boilers, and in regulating the admission of air into furnaces of steam boilers.* Dated April 17, 1863.

These improvements in steam boilers consist in making the boilers conical or tapered in the direction of their length, and with or without a fire-box. The boilers are formed of two conical tubes or cases, one tube being placed within the other. Or a series of tubes are placed within a conical or tapered case. In some cases the patentee adds a third tube, by which the steam may be superheated; or this tube may be made open at the ends, and constitute a water space at pleasure. The invention also consists in placing round the chimney a water cistern for heating the water both with the spent heat and the exhaust steam which passes through a coil or straight pipe; the cistern being kept only two-thirds full, so much of the steam as is not condensed will pass off at an outlet at the top of the chimney and thereby increase the draught. *Patent completed.*

967. R. C. CLAPHAM. *Treating the waste liquors from bleaching powder stills in order to obtain hydrochloric acid and other products therefrom.* Dated April 17, 1863.

The waste liquors above named, which usually contain about one-third of the hydrochloric acid used in the manufacture of bleaching powder, and in an uncombined form, are conducted into a furnace made of brickwork or other suitable material, with heat directly or indirectly applied, as in a blind furnace; or the solutions aforesaid may be distilled in suitable retorts. In either case, the patentee passes the vapours or gases—which consist of hydrochloric acid and steam—through pipes which may be cooled by water, or by the air, or otherwise. Or he passes the gases or vapours through condensers in the usual manner, as well known to manufacturers, and he obtains hydrochloric acid, which generally averages about 15 deg. Twaddle. The acid so obtained is applied in the place of water for muriatic acid condensers, according to the plan recommended for the use of weak muriatic acids in a previous patent of the patentees, dated 11th September, 1860, and by this means he obtains commercial muriatic acid, suitable for the manufacture of bleaching powder, or for other purposes. Or he adds ground manganese to the solution in the furnaces or retorts above described, and after heating a suitable time he obtains chlorine, which may be applied in the manufacture of bleaching powder. The residue left in the furnace or retort consists of chlorides of manganese and iron, and may be variously applied. *Patent completed.*

968. R. H. LAWSON and W. DARLOW. *Improvements in apparatus or means for obtaining motive power.* Dated April 17, 1863.

According to one method of carrying out this invention, the inventors take a box or receptacle of cylindrical form, of about six times the diameter as to length, such box being divided in the centre by a partition, and having the ends made tight by covers. The box is suspended from the centre by suitable pivots, upon which it partially rotates, as required. The pivots are carried by a framing attached to the ground or other foundation, as may be suitable. This tube or box has two holes in it, which are partially closed by two balls or ball valves, and two air-holes are also arranged in the opposite ends of the two divisions. On the top of the tube or box two other tubes or boxes are placed, which the inventors prefer to make about one-fourth of the diameter of the large tube or box; these are fixed on the tube at an angle of about 5 deg. more or less, and they are in length about four and a half times the diameter of the large tube or box; they are fixed so that one end of each tube is directly over and connected with the larger orifice in the box, while the other end of each tube projects beyond the end of each partition or portion into which the tube or box is divided. The end of the box or tube opposite to that where the upper tubes overhang is furnished with a rod or bar of about one and a half times the diameter of the tube or box in length, to which a weight is attached as required. The two upper tubes are open, or partially so, at the outer ends. These tubes are partly filled with a number of pieces or balls of iron, or partly of wood or other suitable substance and partly iron, two of which balls close or partially close the apertures in the tube or box before referred to. The apparatus above described is entirely filled as to the tube or box with mercury (by preference), and is then ready for use. The apparatus is pulled over on its pivots to a certain point by power being applied to the rod or bar attached to the end of the tube; the mercury then enters the small tubes by the apertures therein, and as it enters it causes the pieces of wood, iron, or other material to rise in the small tubes. When they have ascended sufficiently high, the weight of the balls or other pieces of iron causes the tube or box to lose its inclined position, and return to its original horizontal position; on its arrival at such position the mercury in the small tubes runs out into the large box or tube, and is thus made ready for another lifting or tilting operation. These are continued at regular intervals, and the power so obtained may be readily transmitted in any convenient manner, as is well understood. *Patent abandoned.*

969. W. MASSINGHAM. *Improvements in apparatus for cooling liquids.* Dated April 17, 1863.

For the purposes of this invention a rotating fan, mounted on a vertical axis, is employed in order to put the air in motion above the liquids which are contained in a suitable open vessel. The fan carries hollow channels in the form of tubes, or otherwise, which are caused to revolve with the face above the liquids. The forward end of each hollow channel is inclined downwards, so that its forward point or end comes just below the liquids; hence, as the channels revolve, the liquids ascend the inclined ends of the channels, and flow along the same till they arrive at the outlet ends, which it is preferred should be so formed by being perforated or otherwise as to divide the liquids into numerous streams. The forward end of each of the channels is also provided with a bell-mouthed entrance above the inclined parts, by which currents of air are caused to pass along with the liquids through the channels. *Patent abandoned.*

970. C. TURNER. *Improvements in the manufacture of felted fibres.* Dated April 17, 1863.

Heretofore, in the manufacture of felted fabrics, in order to strengthen the fabric and prevent it stretching, threads have been laid in transversely from side to side of the batt. This invention consists in an improved method of laying in these threads. The threads to be laid in are drawn from a frame of bobbins placed at one side of an endless apron on which the batt is carried; the threads pass down from their bobbins through a reed placed parallel with the endless apron, and this reed keeps the threads equally spaced. After passing through the reed, the threads enter a holder, which retains their ends. The holder employed is a comb with teeth set closely together; it is fixed close up to the edge of the endless apron. The threads are taken across the batt by means of a carrier. The carrier employed is a moving comb similar to the holder or fixed comb. The carrier rises up in the space between the reed and the holder comb, and it thus takes the threads as it rises; it lifts the ends of the threads out of the holding comb, and then moving away from the reed and across the endless apron it carries the threads over the batt. The carrier comb then again ascends, and leaves the threads. On each side of the endless apron there is a row of points, which retains the threads in the positions in which they are laid. Between the endless apron and the holder comb there is a knife; it may be an endless band of steel sharpened on the edge, or a rotary knife, and thus cuts off the threads which have been laid across the batt from the bobbins. The operation is continued by the carrier comb returning under the endless apron, and again taking the threads as before. By the time it makes another traverse over the batt, the endless apron with the batt upon it will have travelled a distance equal to the width of the carrier comb, so that the threads will be laid on a portion of the batt immediately succeeding that which received the yarns at the previous traverse. *Patent completed.*

971. B. J. WEBBER. *Improvements in apparatus for separating corn from the ears, and for combing straw.* Dated April 17, 1863.

For the purposes of this invention a platform is used which is arranged to move on axes or pivots at its front edge. At the back edge it is provided with projecting spikes or teeth, the back ends or points of which come nearly to a beating drum or cylinder. On and around the circumference of this drum or cylinder are set rows of teeth or spikes corresponding in length with those on the platform. The spikes or teeth on the drum, as they rotate, pass between the teeth of the platform. The platform is arranged in two parts, so that one man may be causing the straw to be combed, and the grain to be removed from the ears of one bundle or quantity of straw, whilst another man is causing the other end of another bundle of straw to be combed so as to produce reed. The spikes or teeth on the drum or cylinder do not radiate from the centre but incline downwards. The two parts of the platform are each arranged in such manner that its end or edge next the drum or cylinder may be raised and lowered by the foot of the workman. The bundle or quantity of the straw is placed on the platform with the ears towards the cylinder or drum, when the end of the platform next the drum or cylinder is at its highest position, and the workman gradually allows the platform to descend, by which the grain will be removed from the ears, and that end of the bundle or quantity of straw will be combed out. The workman will then reverse the end of the bundle or quantity of straw, and move it on to an intermediate platform, from which the other workman will remove it into the position to have the butt end of the bundle or quantity similarly combed or treated. It will be evident that single machines may be used, and both ends of a bundle or quantity of straw be combed out at the same place. Rotary motion is communicated to the drum or cylinder in any convenient manner by horse power or otherwise. The teeth or spikes of the drum are cleansed of the combings by a revolving axis with teeth. The grain thrashed or removed from the ears is received on to a riddle in the ordinary manner of thrashing machines. *Patent completed.*

972. C. W. and F. SIEMENS. *Improvements in furnaces which are principally applicable to the smelting of iron.* Dated April 18, 1863.

This invention consists in treating coal or other carbonaceous matter for its conversion into coke and combustible gases, either for heating or for illuminating purposes, by means of furnaces of such peculiar construction that, not only is the separation of the gaseous from the solid or carbonaceous constituents of the coal, and in some cases the subsequent total conversion of its carbonaceous constituents into combustible gases, effected in a continuous manner without losing either the combustible gases evolved or the heat residing in the coke while in a state of incandescence, but also the separation of the gaseous constituents, effected with such uniformity, and at such constant temperature that the coal or other material operated upon is converted into gases of considerable heating and illuminating powers, and into coke of superior quality and value to that produced in the ordinary gas retort or breeze ovens; in addition to which substances, such as lignite, peat, and poor coal, may also be made available for the production of comparatively rich combustible or illuminating gases. The invention also consists in so arranging the apparatus that those gases and vapours which are usually formed when the process of distillation is carried on at the temperature heretofore employed, such as light carburetted hydrogen and olefiant gas, the vapours of tar, ammonia, carbonic acid, and others, become decomposed and re-formed under the influence of a white heat into another class of carburetted hydrogens of greater value for illuminating and heating purposes, such as acetylene, propylene, and analogous compounds. *Patent completed.*

973. W. S. MACDONALD. *Improvements in apparatus for drying animal, vegetable, and mineral substances.* Dated April 18, 1863.

This invention consists in drying silk, wool, cotton, hemp, flax, jute, grass, fibre, or leaf, whether in the raw or manufactured state, and minerals or their products, either raw or manufactured, by means of one or more revolving endless or continuous aprons or lappings, between which the substances to be dried are placed, and along with which they pass round a stationary or revolving cylinder or cylinders, heated with steam or otherwise, or over heated steam chests, which endless or continuous aprons or lappings may be made of any material suitable for the quality and condition of the substances to be dried. The aprons or lappings pass over guiding rollers, which, if necessary, may be kept to the proper breadth by pitch chains and tenter teeth or hooks, or any other equivalent methods, to keep the said endless or continuous aprons or lappings distended. *Patent abandoned.*

974. T. A. WESTON. *Improvements in ratchet levers.* Dated April 18, 1863.

In carrying out this invention, large and strong teeth are employed in the ratchet wheels of the said ratchet levers, and the same nicety of adjustment obtained which is usually obtained by fine teeth. *Patent completed.*

975. W. B. BURDEN. *Improvements in wheels and axles, applicable to locomotives, carriages, and paddle wheels.* Dated Aprill 18, 1863.

In carrying out this invention, the inventor proposes to form the arms of the axles of carriage wheels or of other axles whereon the wheels revolve in such manner that they shall be horizontally at right angles to the centre line of the carriage fore and aft, or to the line of progress, the same being vertically declined to the extent, by preference, of 17 degs. and three-fifths, or thereabouts, or not less than 9, nor more than 25 degs. The wheels are to be so constructed that, as they revolve on level ground, each spoke or the medium line of the spokes shall be vertical notwithstanding the vertical declination of the axle, so as to have an upright bearing under the axle, the tyres if flat being horizontal on the ground, but they may be convex or of other sectional form. For locomotives, or for railway carriages where the wheels revolve fixed or keyed on their axles so that their axles revolve with them, the faces of the wheels are to be horizontal on the rail, the centre line of each axle being vertically declined as before described, the bearing of the spokes between the tyres and the axles being upright, whether the faces of the wheels are horizontal or otherwise on level rails. *Patent abandoned.*

976. G. A. BUCHHOLTZ. *Improvements in apparatus for hulling grain, and for reducing granular substances.* Dated April 18, 1863.

This invention has reference to a previous patent, dated Nov. 19, 1862 (No. 3,113). The first part of the present invention relates to an improvement in the hulling machine, and consists in making it of a hollow conical case, which is provided at certain parts throughout its length with converging blades of iron or steel. These blades are set on edge, and are spaced out by thin filling pieces of paper, cardboard, or thin wood, and are arranged longitudinally in the case, so as to present their cutting edges to the grain to be hulled. The best result is obtainable by fitting a portion only of the inner surface of this conical case with these converging blades, the other portions of the case being made up of wire gauze, or perforated metal, which will act as a sieve for the bran or skin that is removed from the grain by the action of the steel blades thereon to fall through. When this case is fitted, a conical runner, provided at its periphery with longitudinal steel blades, is set radially around the runner. The conical runner is made of considerably less length than the case in which it is placed, to allow of its being moved up longitudinally therein into the more contracted portion of the case as the blades are worn away, and the diameter of the runner consequently decreases. In order to break down the hulled grain so as to prepare it for the operation which reduces it to the form of semolina, the patentee proposes, instead of using the crushing rollers described in the specification of the former patent above referred to, to groove one roller longitudinally and the other transversely. This improvement relates to the reducing machine, whereby the hulled and crushed grain is reduced to semolina. It may be described as a vertical conical mill, the cutting surfaces of which are furnished, like the hulling machine already described, with iron or steel blades spaced out by strips of cardboard, paper, or thin wood placed between them. *Patent completed.*

977. T. HUNT. *Improved apparatus for obtaining motive power.* Dated April 18, 1863.

In carrying out this invention, the inventor provides a cylinder, which he mounts on trunnions like the cylinder of

an oscillating engine, and within the cylinder and at the opposite ends thereof he applies two pistons, which he connects together by a parallel motion; or he otherwise arranges them so that the pressure put on the face of the one piston will have a tendency to give a lateral motion to the other piston. The ends of the cylinder he closes in the usual way, and conveys water or other fluid under pressure into the space between the outer face of the pistons and the cylinder ends. This pressure, by being simultaneously applied to the two pistons, will cause them to press edgewise against the opposite sides of the cylinder, and thereby convey rotary motion thereto. *Patent abandoned.*

978. P. G. ROWELL and H. HOLT. *A better and more economical mode of securing the bands of locomotive engine and tender springs, also a new method of applying the same.* Dated April 20, 1863.

Heretofore, the above-named springs, and the leaves composing them, have been much damaged from the bands being driven on hot, and quenched to fix them in their places, and very frequently the leaves break when in action from the unequal pressure upon them. According to this invention, they will not be liable to damage, the bands being put on and fixed cold, and the leaves of the said springs will have india rubber, leather, or other suitable substance placed between them, thus equalizing their pressure one on the other, and also from their being drawn tight they will not get displaced when in action. *Patent completed.*

979. C. RANDOLPH and J. ELDER. *Improvements in surface condensers.* Dated April 20, 1863.

This invention relates to surface condensers of the kind having a series of tubes in a casing, and comprises improved means of holding the tubes in the tube plates. In carrying out this invention, according to one modification, short tubes or ferules are fixed in the tube plate, so as to project a little on the outer side, and the condenser tubes are passed through these fixed tubes, being made of such a length as to project a little beyond their outer ends. There is then passed on the end of each condenser tube and fixed tube a short tube of an elastic material, such as vulcanized rubber, which grasps both and makes a water-tight joint, without hindering the slight movements caused by the expansion and contraction of the metal. *Patent abandoned.*

980. G., W., and J. GRAHAM. *Improvements in machinery for folding or plaiting fabrics.* Dated April 20, 1863.

This invention relates to a new or improved machine for folding or plaiting silk, cotton, woollen, linen, or other woven fabrics into straight, even, and equal folds of from 12 in. to 2 yards, or more if required. Instead of a horizontal or curved table, the inventors use a vertical frame or bar, or a series of frames or bars, supported in bearings at each end of the machine, or from the floor or otherwise, on the upper edge of which the cloth is laid, an equal length of cloth being made to fall down on each side of the frame or bar by means of a vibrating cage working in the arc of the circle over the vertical frame or bar, or upon horizontal guide bars. A footboard, friction bars, handles for starting and stopping, strap guide and bar rods, break wheel, brushes, sloping board, and guide rod, with sliding collars, adjustable by set screws, or other convenient arrangement, may be used as in the present ordinary plaiting machines. *Patent abandoned.*

981. C. BLANC. *Improvements in apparatus for the purpose of using air and steam as motive power.* Dated April 20, 1863.

This invention relates to apparatus having for its object to combine the elastic forces of the atmospheric air and steam, so as to obtain thereby increase of power with economy of fuel and water. As arranged by the patentee, the apparatus is provided with small double-acting pumps, of which there may be one or more in connection with the upper portion of the apparatus, and a corresponding number in connection with the lower portion of the apparatus. The pump or pumps in connection with the upper portion of the apparatus are for the purpose of forcing atmospheric air into such apparatus, partially to condense the exhaust steam conducted therein by a suitable pipe or passage from the cylinder of the engine with which such apparatus is in connection. The pump or pumps in connection with the lower part of the apparatus serve to draw therefrom the partially condensed steam and atmospheric air, and force them into the boiler or generator through pipes suitably arranged for that purpose. These pumps may be worked by the engine with which they are used. *Patent* fluids will continually flow, separated from the matters with which they are previously mixed or combined. When the more solid matters fill, or for the most part fill, the first compartment, they are to be removed therefrom, and such matters will be found to be arranged within such compartment in the order of their specific gravities; thus, by this apparatus, in those cases where the liquids are such as will become clear by subsidence, such liquids will be separated in a clear or more or less clear state, whilst the matters heavier and lighter than the fluids with which they were previously mixed or combined will be retained back separated from the fluids. *Patent abandoned.*

983. W. E. NEWTON. *Improvements in lamps.* (A communication.) Dated April 20, 1863.

This invention is not described apart from the drawings. *Patent completed.*

984. E. W. HUGHES. *Improvements in turn-tables, turn-bridges, and slips.* Dated April 20, 1863.

This invention is not described apart from the drawings. *Patent completed.*

985. A. FORD and R. RIGG. *An improved method of re-forming and re-using old or waste vulcanized india rubber.* Dated April 21, 1863.

The patentees claims—1, the preparing of vulcanized india rubber, when in a state of fine division, and without any previous annealing or amalgamating, in moulds for the purpose of its being subsequently submitted to the action of heat; 2, the re-moulding and re-vulcanizing india rubber without the aid or necessary admixture of any of the new or unvulcanized india rubber. *Patent completed.*

986. H. RAFTEN. *An improved process for obtaining printing surfaces.* Dated April 21, 1863.

This process for obtaining printing surfaces is founded on the elasticity of a sheet or film of india rubber, or similar elastic gum or substance, which is made in certain parts to adhere to a plate or sheet of a porous, permeable, or pervious and comparatively non-elastic material, or some non-elastic material that is made permeable or pervious in the parts not required to adhere. A fluid is then made to pass through this non-elastic plate or sheet, with a certain degree of pressure, which expands the elastic sheet or film in those parts not adhering. As long as the pressure is continued, these parts are found projecting in convex surfaces from the non-elastic plate or sheet, and the surface of the elastic sheet or film in this state being made conducting with a coat of plumbago, an electrotype can be taken which will be the printing surface required. *Patent completed.*

987. J. HEAP. *Improvements in adjustable wrenches for nuts, pipes, and pins.* Dated April 21, 1863.

The first of these improvements consists in constructing wrenches of a new form, the handle being made so as to be lengthened at pleasure, by which means an additional leverage or power can at all times be obtained, and which is of great importance when the instrument is to be applied to nuts, pins, or pipes of varying dimensions. The inventor effects this improvement by having the handle made of a hollow piece of round iron or pipe, which is screwed or tapped inside with a thread to correspond with the thread of the screw on the contrary end of the head or jaw of the instrument. The handle is made larger in circumference next the screw than the screw itself, by which means it operates as a flange and regulates the sliding box. Another part of the improvements consists in making the head or jaw of the instrument with a tail screw to work into the screw of the handle, the part next above the screw being made square or four-sided, on which is placed the slide box with a tongue or catch working on a pivot or centre pin fixed on a projection or nib on the upper side of the slide box, which is acted upon by a spring attached to the tongue or nib. The second improvements consist into constructing nut wrenches with a screw of solid metal, and with pivots at each end, which turn in bearings composed of two small plates let into grooves in the head of the key. *Patent abandoned.*

988. E. L. SIMPSON. *An improvement in waterproof compounds, and in fabrics prepared therewith.* Dated April 21, 1863.

This invention consists in producing a compound free from sulphur or sulphurous ingredients, which, when applied, will render the articles or fabrics to which it is applied impervious to air or water, and free from the offensive odour arising from sulphured or vulcanized goods. vessel, and consequent oscillating motions of the governor, have no influence on the position of the throttle valve. The invention consists, finally, in placing the rod which transmits the motion of the balls to the valve loosely on the top of the rising-and-falling rod, leaving the latter perfectly free to accommodate itself to the varying position of the vessel without disturbing its connection with the said rod. *Patent completed.*

991. J. W. NOTTINGHAM. *Improvements in two-wheeled vehicles.* Dated April 21, 1863.

According to this invention the width of the body of the vehicle is extended, the springs disposed within the limits of the breadth, and beneath it, whereby a more commodious vehicle is obtained. By widening the body more room is also obtained for entering and alighting from the vehicle. As a further improvement to facilitate the entering and alighting from a vehicle, the inventor makes the doors to occupy nearly the full width of the body; and in order to render them easy of movement, as also to occupy a convenient space when open, he makes each half or part of the door in two or more pieces, hinged together so that they may be folded or rolled, if necessary, the one piece on the other, or be folded and disposed between the wheel and the body. The fourth part of the improvements relates to the head, which, instead of being a fixture, as usual, he makes separate from the body, and mounts it thereon on a pivot at each side, so that it rises and falls somewhat in the manner of a folding carriage head; but in this case the head is rigid, similar to the head of an ordinary cab. *Patent abandoned.*

992. H., E., S., and J. YEADON. *Improved healds for weaving.* Dated April 21, 1863.

These improved healds are made of steel, iron, brass, zinc, or other suitable substance, such healds also termed eyelets consisting of bars, strips, or pieces. The said eyelets or healds are made with one, two, three, or more holes or orifices through the same, with any form of eye, whether circular, square, or otherwise, as may be desired. These healds or eyelet pieces are arranged in or on frames of cast iron, or other substance, their ends being secured on steel or other wires or rods, which are fastened and tightened by means of the threads on the ends of the said wires or rods, provided with nuts correspondingly threaded, and these healds or eyelets will facilitate the weaver in tying the threads with ease, and secure facility of passing of the threads of the warp. Instead of making the healds or eyelet-pieces in the manner before mentioned, they may be made with one of the ends of each placed between pieces of wood, or other suitable material, secured together, and thus fastening the healds or eyelet pieces in position by pitch or such like adhesive and cohesive material, holes being provided in the middle of the pieces. *Patent completed.*

993. H. DONALD. *Improvements in machinery or apparatus for bending or straightening metal plates.* Dated April 21, 1863.

The patentee claims—1, the general arrangement and construction of rolling mills or machines for bending or straightening metal plates essentially as described; 2, the introduction and use of an intermediate roller of small diameter between the upper roller and the two lower rollers on rolling machines of this class, and for the purposes described; 3, the forming of the rollers of such mills or machines with angular or V-shaped grooves as described. *Patent completed.*

994. W. E. NEWTON. *Improvements in wrenches.* (A communication.) Dated April 21, 1863.

This invention relates to the construction of improved self-acting wrenches for screwing and unscrewing nuts of any shape or dimensions, whether circular, square, hexagonal, or of other form, and for screwing and unscrewing gas pipes and other articles requiring such an operation. The improved wrench may be formed with two jaws, or with a double pair of jaws, which, if desired, may differ in size and strength. One of the jaws is fixed firmly, while the other, which is moveable, slides in a forked part of the fixed jaw. The pressure against the moveable jaw is exerted by means of a lever or arm, which turns on a pin fixed in the stationary jaw, and is connected to the moveable jaw by a link. By pulling forward the lever, the nut will be firmly gripped between the jaws. The pressure exerted will correspond with the amount of force applied for turning the main lever, and will increase if nuts of smaller size are gripped. *Patent completed.*

vertical links of a chain harrow, leaving at the same time a more clean and fine tilth. *Patent completed.*

996. W. CAMPION and G. WILSON. *Improvements in machinery or apparatus employed in the manufacture of looped fabrics.* Dated April 21, 1863.

We cannot here give space to the details of this invention. *Patent completed.*

997. W. RYAN and W. DANIEL. *Improvements in apparatus for transmitting, equalizing, and registering human power.* Dated April 21, 1863.

The power which this apparatus transmits may be used for driving pumps, grinding grain, and various other purposes for which motive power is required. The apparatus is especially suitable for use in prisons, and is so arranged that, if any one labourer of a number (set to work it) should cease working, he will not necessarily interrupt the others, nor even hinder them, except in so far as his cessation of work may reduce the amount of combined power, and such cessation of work will be at once signalled to his companions and to the person superintending. The framework of the apparatus forms a number of compartments or divisions, one for each man; they are so contrived that each labourer is separated from the others. In each division or compartment is a crank, one for each man to work; motive power is communicated by these cranks to a main shaft, which extends the whole length of the apparatus, and is common to and in connection with all the cranks. This shaft transmits the motive power which it receives to a pump, mill, or other engine, machine, or apparatus to be driven. The cranks communicate their power to the main shaft as follows:—Through each partition or division that forms the compartments is fitted a short shaft projecting at one end into one compartment, and at the other end into the adjoining compartment, so that two such short shafts project into each compartment, one at one side thereof, and one at the opposite side. Each short shaft has at one end a ratchet, and each crank has at the end of one of its arms a pall for driving such ratchet. The opposite end or arm of the crank works loosely on the end of the other short shaft—that is to say, each crank has on one arm a pall for engaging a ratchet and short shaft at one side, and its other works loose on a short shaft at the other side. On each short shaft is a toothed wheel in gear with a toothed wheel on the main shaft. It follows that when the labourers work the cranks, the palls will drive the ratchets, and these will actuate the toothed gearing, and thus communicate motion to the main shaft; but if one of the labourers should cease working while others are at work, the ratchet of his crank will travel over his idle pall, and produce a noise which will signalize the cessation of work in his compartment. The main shaft also actuates a registering apparatus placed at one end of such shaft; it is so fitted that the labourer cannot get at it to tamper with it. It gives notice when a certain quantity of work has been performed, so that when labourers are employed in relays, each relay may accomplish an equal quantity of work. This registering apparatus consists of a case in which are two endless screws, in gear with pinions or wheels so arranged that at certain intervals of time—that is to say, when a certain number of revolutions of the main shaft have been performed—they cause a bar, arm, or lever to strike a bell; or they may work an index pointer, or both work a pointer and strike a bell. *Patent completed.*

998. F. E. BRYANT. *Improved apparatus for ascertaining the temperature of steam and its power of tension.* (A communication.) Dated April 22, 1863.

This invention is not described apart from the drawings. *Patent completed.*

999. T. SETTLE. *Certain improvements in flyers to be employed in roving, slubbing, and spinning cotton and other fibrous substances.* Dated April 22, 1863.

This invention relates to a novel method of securing the flyers upon the spindles employed in machinery for roving, slubbing, and spinning cotton and other fibrous substances, and consists in forming a long vertical "key" or rib in a suitable position in the interior of the flyer tube in which the spindle fits, in contradistinction to the use of a short stud as hitherto employed, and which does not form a sufficiently perfect union between the spindle and flyer. The top of the spindle is grooved vertically into any required number of recesses, into which the said long "key" or rib falls, and so secures the flyer on the top of the spindle. The chief feature in the invention is the elongated form and position of the "key" by the lengthened bearing or surface of which a better and steadier hold is effected between the spindle and flyer. *Patent completed.*

1000. F. DURAND. *Improvements in moulding articles of china or other clay, or of other plastic materials.* Dated April 22, 1863.

This invention is not be described apart from the drawings. *Patent completed.*

1001. T. GRACE. *Improvements in reaping and mowing machines, part of which improvements is applicable to other useful purposes.* Dated April 22, 1863.

This invention consists—1, of a novel form and arrangement of apparatus for raking and delivering the cut corn (or grass) from the machine. On one end of the shaft of the travelling wheels there is a bevel wheel, which takes into a bevel pinion on a longitudinal shaft at one side of the platform of the machine. On this shaft there are three pulleys, connected by endless chains or belts with three corresponding pulleys on the opposite side of the platform. These endless chains, by means of suitable snugs, give motion to a cross piece, and cause it to traverse backward and forward from side to side of the machine. This cross piece carries with it three (or more) rakes or teeth, which are held in a vertical position whilst raking off the corn, but in the return movement they lie horizontally under the platform. By the alternating motion of the teeth or rakes the cut corn (or grass) is swept from the platform and delivered in a sheaf at the side of the machine. At the delivery side of the platform there are teeth to prevent the corn from being raked off until a sufficient quantity has been coll[illegible] form a sheaf. These teeth are held in a vertical position by a catch which is released by the action of the machine when a sufficient quantity of corn has been gathered. 2, In the use of a driving band for giving motion to the cutting knives. *Patent abandoned.*

1002. H. B. BARLOW. *Improvements in shoes, boots, and other coverings for the feet.* (A communication.) Dated April 22, 1863.

This invention consists in the application of a plate or plates of a peculiar form, made of malleable cast iron or other metal or material, to the toes of shoes, boots, and other coverings for the feet to render them more durable. The plates form a sheath or fender both for the protection of the upper and under leather at the toe of the boot, shoe, or other covering for the feet. The said sheath or fender is formed of compounded metals, and may be composed of a mixture of lead, tin, and bismuth, or any of the known metals or preparations, such as india rubber, gutta percha, or other substances which are sufficiently sequacious to be wrought or moulded into the desired form. The said sheath has a double form, being a union of the covering for the upper and under leather in one entire piece of metal or other substance of which it may be constructed. The form is such that it covers over the upper leather at the toe, and extends downwards over the outer sole, and passes over on the outer side of the said sole sufficient to receive the nails to fasten it on and has also a central flange which passes between the outer and inner sole extending back towards the heel. *Patent abandoned.*

1003. E. J. JEFFS and J. TURNER. *Improvements in the making and constructing carriage ways.* Dated April 22, 1863.

This invention consists in supporting the granite pitchers forming the surface of the road on sleepers, which may be of wood creosoted or otherwise, or of iron or wood combined, of any form, as may be thought most desirable, and of any suitable length, which sleepers may be laid longitudinally or diagonally; or there may be two layers of sleepers running at right angles to each other. *Patent abandoned.*

1004. W. CLARK. *Improvements in the means of obtaining publicity.* (A communication.) Dated April 23, 1863.

Provisional protection has not been allowed for this invention.

1005. J. LEE and E. DAWSON. *Improvements in looms for weaving.* Dated April 22, 1863.

The objects of this invention are—1, to hold out the cloth or fabric while in the act of weaving better than heretofore, and thus reduce the friction on the yarn or warp threads by the reed, and thereby prevent a great amount of breakage of yarn; 2, to keep the cloth or fabric in a straight line, and impart to the selvages a forward as well as an outward motion, so that they are kept tight, and thereby enabled to resist the drag of the weft which takes place when the shuttle is thrown from one side of the fabric to the other, by which means a more even selvage is obtained. The improvements consist in the employment of one or more screwed rollers, with right and left threads, either of the ordinary V-kind, or round-topped, and with single, double, or more threads, to present a greater or less angle to the cloth or fabric. The said screwed roller or rollers is or are placed in a suitable frame or frames, bolted or otherwise fastened to any convenient part of the loom, so that the screwed roller or rollers may be brought in contact with each side of the cloth or fabric, and driven by an intermittent motion, transmitted from any working part of the loom, through or by wheels, levers, springs, weights, chains, or any other suitable appliances which will drive the screwed roller or rollers at a greater speed than at which the cloth or fabric is made. The patentees also employ a roller or rollers covered with a soft yielding substance, such as india rubber, gutta percha, leather, or other suitable material, which roller or rollers is or are placed in the frame above mentioned, but on the opposite side of the fabric to that of the screwed roller or rollers, and acts or act to press the cloth against the screwed rollers to give them sufficient hold on the cloth to produce the outward and forward motion before mentioned. *Patent completed.*

1006. G. B. BARBER. *Improvements in steam boilers and apparatus connected therewith.* Dated April 22, 1863.

This invention is not described apart from the drawings. *Patent completed.*

1007. J. W. PROFFITT and W. L. DUNCAN. *An improved mode and apparatus for distributing sand or any other suitable substance or substances on the rails of railways and tramways.* Dated April 23, 1863.

This invention is not described apart from the drawings. *Patent completed.*

1008. J. WHITLEY, J. POPE, and J. W. BURTON. *Improvements in the manufacture of metals.* Dated April 23, 1863.

In carrying out this invention, the inventors generate steam from water mixed with hydro-carbon oils, and pass the vapours through charcoal at a red heat, which vapours they use in conjunction with the atmospheric air, or apart from it, in smelting or refining iron, copper, and other metals containing sulphur. *Patent abandoned.*

1009. R. RICHARDSON. *Improvements in railway permanent way.* Dated April 23, 1863.

This invention consists in new descriptions of railway sleepers, and a new method of fastening the rails on those sleepers. The sleepers are constructed of cast or wrought iron, or wood, or of any or all of those materials, in combination with cheeks, jaws, or chairs arranged in such manner that they receive keys placed on both sides of the rails alternately, or two or more on each side of the rails alternately, and by the assistance of those cheeks, jaws, or chairs on those sleepers the rails are held firmly in place throughout the line, including the joints of the rails, by a system of alternate keying. The improvements also consist in new cast or wrought-iron chairs or jaws to be attached to sleepers of such form that the rails are secured by alternate keying, as before described. *Patent completed.*

1010. W. E. NEWTON. *An improved mode of repairing worn-out files, and rendering them again fit for use.* (A communication.) Dated April 23, 1863.

This invention consists—1, in cleaning the file and removing from the surface in any convenient manner all organic, mineral, or other matter that may adhere thereto, and then placing the file in a bath of diluted sulphuric, nitric, or other corrosive acid, and allowing it to remain therein until the acid has bitten down into the metal and sharpened the teeth. When the teeth have been re-formed and brought to a point, the file must be taken out of the acid bath, washed in clean water, and then well brushed with pulverized charcoal or ashes, after which the file may be greased over in order to protect it from rust. *Patent completed.*

1011. W. CLARK. *Improvements in the manufacture of tiles; and in apparatus for the same.* (A communication.) Dated April 23, 1863.

This invention consists—1, of cylinders having circular grooves, and gearing one with the other, for cutting up and crushing the material to be used. 2, The apparatus is furnished with a pressing box and draw plate, which receives the material from the cylinders, and draws it out so as to form a cake or sheet, which is then hardened by pressure exerted by an eccentric receiving motion from a piston to which it is jointed. 3, The apparatus is furnished with a cast-iron mould for receiving the sheet of clay in order to form the tiles. This mould is placed in a press acting vertically, in which the sheet of clay receives an energetic pressure, which reduces it one-third of its thickness, and so causes it to take the exact form of the cast-iron mould. Tiles manufactured in this way are then trimmed round and exposed for a few days only to the air, in order to partially dry them, after which they are placed in ovens to be baked as in ordinary. *Patent completed.*

1012. T. RICHARDSON and J. C. STEVENSON. *Improvements in the manufacture of sulphate of soda.* Dated April 23, 1863.

In the manufacture of soda in alkali works, common salt and sulphuric acid are mixed together in a decomposing pan; but the salt is used at the ordinary temperature, and the sulphuric acid is generally heated before being mixed with the salt. This invention consists in heating the salt by any convenient method before mixing it with the acid. In order to prevent evaporation of the sulphuric acid, the temperature of the heated salt must not exceed the boiling point of the sulphuric acid employed. *Patent completed.*

1013. P. MCGREGOR. *Improvements in machinery for spinning and doubling.* Dated April 23, 1863.

This invention consists—1, in an improved arrangement and combination of machinery for effecting the second draw in mules; 2, in making the cam for throwing the rollers out and in gear in two pieces, whereby the working parts may varied in the relative positions at pleasure; 3, in an arrangement and combination of machinery for pulling the building faller-wire closer to the spindle-point as the cop gradually increases in length for diminishing the amount of backing-off in the set fills. In connection therewith the patentee makes the scroll for pulling down the faller the reverse way to that generally adopted. 4, in an arrangement and combination of machinery for throwing suddenly into gear the catch-wheel and catch, or the clutch box, for working the screw of the radial arm and raising the nut or point of attachment of the winding-on chain. 5, in an arrangement of machinery connected with the builder for throwing the catch boxes for driving the front drawing roller into gear, so that as the cop increases in length, the rollers are later in starting. 6, in a mode of attaching the winding-on chain to the radial arm, whereby a more beneficial action is produced on the winding-on as the cop increases in diameter. 7, when two scrolls are used for taking in the carriage, the patentee connects the bands of both scrolls to a double lever mounted on a stud attached to the carriage, so that both bands are kept at a uniform tension. And, lastly, in certain improved combinations and arrangements of self-acting machinery for tightening the winding-on chain, as the carriage goes in towards the beam. *Patent completed.*

1014. J. CAVANAH. *An improvement in cricket bats.* Dated April 24, 1863.

This invention consists in manufacturing a loose handle for cricket bats, and the joining of the same to the blade in conjunction with a spring. The loose handle is secured to the upper part or mouth of the blade of the bat by a hinge or knee joint; attached is a spiral or flat spring, made of steel, india rubber, or any other suitable elastic substance, fixed with metal plates and sockets to the blade and handle. The spring may be applied or attached to such portion of the blade or handle as may be found most desirable; its employment prevents the concussion of the ball stinging or jarring the hand. *Patent completed.*

1015. J. B. DAINES. *Improvements in the preparation of stone, plaster, compo, iron, wood, and such like substances, so as to preserve them from decay.* Dated April 24, 1863.

According to this invention, the patentee first prepares a solution by mixing together animal gall, liquor calcis, and liquor from boiling potatoes; these he prefers to mix in the following proportions—namely, one point of gall to one gallon of each of the other liquors. This solution he names solution No. 1. He next proposes a solution of sulphur and camphor, obtained by the use of a combination of mineral and linseed oils, or other suitable solvent compatible with the nature of the material under treatment; as, for instance, when stone or such like surfaces are to be treated with this composition, he prefers to use three parts by weight of linseed oil to one part by weight of purified mineral oil. When rough surfaces of iron, wood, stucco, and such like surfaces are under treatment, he prefers to use crude mineral oil together with a little of the lighter oil in order to reduce its consistency. In some

cases cheap fat oils may be used when they can be obtained; but in this case, as with the mineral oils, and sometimes with the linseed oils, to facilitate their drying quickly, it is necessary to use dryers, as is well known to painters. The quantity of sulphur is made to vary according to the purposes to which the compositions are to be applied. For saturating the surfaces of stone, the patentee prefers them to have in solution about one-sixteenth of their weight of sulphur; this is obtained by heating the oils with the flour of sulphur to the temperature of 278 deg. Fahr. When rough surfaces of iron, wood, stucco, and such like surfaces are under treatment, he prefers the compositions to contain a larger per-centage of sulphur than for the surfaces of stone. In these combinations the use of camphor varies considerably, depending upon the nature of the material to be treated, and the purposes to which it is to be applied; as, for instance, with wood and iron when exposed to damp or to dry-rot, he prefers these combinations to contain one-seventieth of their weight of camphor, and when not exposed to such actions, a smaller quantity may be employed. In certain cases he has found a small quantity of creosote to be advantageous where the camphor is used. The above solutions or compositions he names No. 2. The mode of treatment is as follows:—The surfaces of the stone, plaster, compo, wood, iron, and such like substances having been cleansed, when necessary by a solution of an alkali, and the alkali neutralized by a very weak acid, and thoroughly washed with water, he applies each of these solutions by the aid of a brush, in the same manner as painting, or by some such similar manner, to their surfaces; but, in the case of timber for ships, or other uses, statuary, and other portable articles, where it may be desirable to thoroughly saturate them, these solutions as required, No. 1 and No. 2, may be injected by means of an exhausted receiver. *Patent completed.*

1016. W. N. WILSON and J. G. GREY. *Improvements in machinery for sewing and stitching.* Dated April 24, 1863.

This invention relates to the combining of certain new and useful contrivances in what is technically termed the feed motion to those machines which are now in use, and which are adapted to what is called the four-feed motion machine. Instead of confining the four-feed motion to its up, forward, down, and backward motion only, to direct the cloth in a line at right angles with the body of the machine, and which feeds one way, the patentees use what is called a reverse movement attached to the said feed motion, which throws the feeding lever from the cams which actuate it for one direction, and brings it into contact with other cams, which actuate it for feeding in another direction, so that the up, forward, down, and backward motion of the feed is moved at right angles one from the other, thereby sewing lines of stitches at right angles to each other without turning round the cloth. *Patent completed.*

1017. J. LAMBERT. *Improvements in ball cocks.* Dated April 24, 1863.

This invention consists in constructing ball cocks as hereafter explained. The inventor makes the inlet and outlet passages lead into and out of a cylindrical chamber, the bottom of which forms the seat for a circular disc, under which a leather or other like suitable washer is placed. The disc is formed or fixed on the lower end of a spindle, which works through an aperture made in the cover of the chamber; a spring, by preference, in the form of a disc of vulcanized india rubber, is also fitted to the spindle inside the chamber, which balances the valve and prevents any liquid escaping through the top or upper part of the chamber. The rising of the ball or float on the long arm of the float-lever—the short arm of which is connected to the valve spindle—depresses the short arm, which forces the spindle down, and keeps the valve on its seat, so as to close all passage through the cock. Upon the ball or float falling, it raises the spindle and the valve off its seat, and opens up a way through the cock. *Patent abandoned.*

1018. J. SHEPPARD. *Improvements in steam engines.* Dated April 24, 1863.

According to this invention, an outer or fixed cylinder of a suitable diameter is employed, and in the interior thereof, and concentric with it, the inventor places another cylinder or drum of smaller diameter, capable of revolving, and keyed upon the shaft to be driven, the central line of which shaft passes through the axes of both cylinders, which are coincident with it, and with each other. To the face of the inner or revolving cylinder is fixed a piston plate, projecting in a radial direction therefrom, and fitting the space between the two cylinders. On opposite sides of the outer or fixed cylinder are two semi-cylindrical recesses of the same width as the cylinder (one upon each side), their radius being rather more than equal to the distance between the two cylinders, and their axes being parallel to the central shaft. Inside these recesses are placed semi-cylindrical or conical-formed blocks, mounted on shafts, and capable of revolving, being connected by cranks and spur wheels to the central shaft, so as to revolve at the same speed, but in an opposite direction to the other. The revolution of these crescent-formed blocks is so timed that each one presents its hollow face at the time the piston-plate is passing it; whilst the opposite one is revolving in contact with the inner cylinder, and acting as a steam-stop, the whole being made steam-tight by suitable packing. The valves are opened and closed so as to admit and cut off the steam at the required intervals by two eccentrics keyed upon the central shaft. *Patent abandoned.*

PROVISIONAL PROTECTIONS.

Dated August 24, 1863.

2093. L. Guillemot, 42, Rue du Moulin à Vent à Poitiers, Département de la Vienne, France. An improved machine for obtaining perpetual motion.

Dated September 25, 1863.

2362. C. de Wailly, No. 1A, Florence-street, Upper-street, Islington. An improved slipper or clog, principally intended for bath rooms.

Dated October 10, 1863.

2486. S. Banner, Liverpool, general broker. An improved mode or method of storing petroleum and other like oils and spirits.

Dated October 12, 1863.

2502. C. Humfrey, St. David's Works, Saltney. Improvements in the means and method of purifying hydrocarbons.

2504. G. Mountford, Brunswick-street, Leeds, manager. An improved construction of cotton gin.

Dated October 14, 1863.

2523. R. H. Smithett, King's Bench-walk, Temple, student-at-law. Improvements in the application of wheels to railway carriages.

Dated October 15, 1863.

2530. S. Flexen, 46, Skinner-street, Snow-hill. An improved apparatus for ventilating railway and other carriages, houses, buildings, steam and sailing vessels of all kinds, moveable or otherwise.

Dated October 17, 1863.

2543. Y. Meirat, Henry-street, Hampstead-road. Improvements in the means of propelling vessels.

Dated October 22, 1863.

2595. J. Craven and S. Fox, Leeds, engineers. Improvements in machinery or apparatus for punching, shearing, and burnishing.

Dated October 23, 1863.

2612. B. Marriott, 38, Upper-street, Islington, watchmaker. An improvement in watches, consisting in the construction of cylindrical dead beat independent centre seconds watches.

Dated October 27, 1863.

2650. J. C. Wilson, 14A, Cannon-street, civil and mechanical engineer. A new mode of mounting ordnance, and the machinery and apparatus composing the same, also the machinery and apparatus for working said ordnance, and for loading, cleaning, and counteracting the recoil when fired.

2652. E. G. Atherley, Orme-square, Bayswater, barrister-at-law. Obtaining motive power by certain arrangements of machinery and water.

Dated October 30, 1863.

2682. J. Haworth, 15, Hart-street, Bloomsbury, gentleman. Improvements in the improved method of conveying electric signals and telegrams without the intervention of any continuous artificial conductor.

2683. F. Durand, Paris, mechanical engineer. Improvements in cotton gins.

2690. B. Russ, Bristol, engineer. Improvements in the construction of iron and other ships, vessels, and batteries of war, and of cupolas and armour plates applicable thereto, parts of which improvements are also applicable to other useful purposes.

Dated October 31, 1863.

2698. A. Wasserburgen, 9, Calvert street, Shoreditch, merchant, and T. Bessunger, merchant. Improvements in the manufacture of show cards, window tickets, and ornamental labels as advertising mediums.

2699. S. H. Parkes, Birmingham, manufacturer. Improvements in opera glasses, telescopes, microscopes, spectacles, and other optical instruments.

2700. W. Tasker, Waterloo Iron Works, Upper Clatford, Southampton. Improvements in the making of safety paper, and in the machinery or apparatus employed therein.

2706. J. Wilson, Upper Poppleton, Yorkshire. Improvements in thrashing machines.

2707. S. Holman, 18, Cannon-street, City, engineer. Improvements in machinery for raising and forcing fluids, parts of which improvements are also applicable to steam engines, blast engines, exhausters, and other machines.

Dated November 2, 1863.

2710. F. J. Vandenvinne, 37, Rue aux Laines, Brussels, manufacturer. Improvements in machinery for excavating land, making cuttings, and other earthworks.

2712. T. F. Wintour, Clifton, near Bristol, esquire. Improvements in ventilators and fire-guards.

Dated November 3, 1863.

2713. T. W. Alderton, Ipswich, machinist. Improvements in sewing machines.

2714. F. J. Pastorelli, 208, Piccadilly, optician. Improvements in the construction of surveyors' levels and other surveying instruments.

2718. S. Bateman, Asnieres, France. Improvements in machinery for combing wool and other fibrous substances.

2720. J. J. Révy, 28, Grosvenor-street, Eaton-square, civil engineer. Improvements in the manufacture of explosive compounds.

2721. M. Henry, 84, Fleet-street. Improvements in the manufacture of zinc white. (A communication.)

Dated November 4, 1863.

2722. J. Livesey, 75, Cannon-street West, and J. Edwards, 29, Basinghall-street. Improvements in the permanent way of railways, and fastenings for the same.

2724. G. Ville, Paris, professor at the Museum of Natural History. Improvements in treating natural phosphates of lime for agricultural purposes.

2726. E. Hughes, Bagillt, Flint. Improvements in fans for forcing and exhausting air or other gases.

2727. C. Howe, jun., New York. Improvements in sewing machines.

2730. A. Gillett, Highway Farm, Berks, engineer. Improvements in machines for cutting chaff and such like substances.

2732. J. H. Maw, Broseley, Salop, gentleman. Improvements in the application of preservative coatings or compositions to the bottoms of ships and vessels.

Dated November 5, 1863.

2736. J. Northrop, Thornton, near Bradford, Yorkshire. An improved apparatus for making fringes.

2737. E. K. Dutton, Stretford, Chester, mechanical engineer. Certain improvements in apparatus for coating or covering the surfaces of rollers or cylinders with leather or other material.

2738. T. Farra, Manchester, salesman. Certain improvements in "skirtings" employed as wearing apparel.

2741. W. Proger, George-street, Middlesex, tin plate worker. Improvements in lanterns, and lamps for the same.

2742. H. Hancock, 28, Clayland's-road, Clapham-road, and W. H. Vickers, jun., 24, Blackman-street, Borough. A new system of fastening for doors, windows, safes, chests, and other similar purposes.

2743. J. Whitworth, Manchester. Improvements in the treatment and application of steel and homogeneous metal.

2744. H. Bessemer, Queen-street-place, New Cannon-street. Improvements in the manufacture of railway bars.

2745. S. Smith, Hyson Green Brass Works, near Nottingham. Improvements in safety valves for steam boilers, and in valves and taps for regulating the flow of fluids.

2746. H. Bessemer, Queen-street-place, New Cannon-street. Improvements in the manufacture of malleable iron and steel, and in the apparatus employed in such manufacture.

2747. R. T. Tait, 10, Essex-street, Strand. Improvements in the manufacture of woollen garments.

2748. G. Speight, 5, St. John-street-road, Clerkenwell, manufacturer. An improvement in collars and cuffs.

2749. F. E. Sickles, New York, engineer. An improved mode of, and apparatus for, steering and turning vessels.

Dated November 6, 1863.

2750. C. D. Abel, 20, Southampton-buildings, Chancery-lane. Improvements in fluid meters. (A communication.)

2751. C. Coates, Sunnyside, Lancashire, engineer. Certain improvements in machinery for printing cotton and other fabrics.

2753. J. Muckart, Letham-mill, near Arbroath. Improvements in preserving certain vegetable substances.

2754. W. Davies and G. Cate, both of 151, North-street, Old-road, Stepney, cork cutters. Improvements in machinery for cutting corks, bungs, gun wads, and other similar articles.

2755. C. H. Southall and R. Heap, Staleybridge, Lancashire. Improvements in self-acting machinery or apparatus worked by steam or other power, for cutting and shaping the soles and heels of boots and shoes, and screwing them on to the uppers or coverings, and also in vices for holding the same, and tools for paring, blacking, and glazing, or otherwise ornamenting the edges of the soles and heels.

2757. J. S. Guirette, Paris, doctor of medicine. An improved inhaling apparatus.

2758. J. Townsend, Glasgow, manufacturing chemist. Improvements in the manufacture of nitrate of potash.

2759. W. M. Neilson, Glasgow, engineer. Improvements in axle-boxes. (Partly a communication.)

2761. C. M. Campbell, Stoke-upon-Trent, esquire. Improvements in apparatus for drying plates and other articles of china and earthenware.

2762. W. H. Perkin, Seymour-villa, Sudbury. Improvements in the manufacture of colouring matters suitable for dyeing and printing.

2763. R. Johnson, Manchester, iron and wire manufacturer. Improvements in testing the strength of wire for telegraphic and other purposes.

Dated November 7, 1863.

2765. H. L. Emery, 72, Sloane-street, Chelsea, agricultural implement maker. Improvements in machinery for ginning and cleaning cotton, a part of which are applicable to machines for other purposes.

2766. T. C. Barraclough, Manchester, engineer. Certain improvements in looms for weaving. (A communication.)

2767. R. Batt, Waterhouse-mill, Milnthorpe, Westmoreland, paper manufacturer. Improved arrangements of paper-making machinery.

2769. J. Johnson, Peterborough, engineer. Improvements in apparatus for lubricating the cylinders and other parts of steam-engines.

2771. L. Braham, Hatton-garden, London, optician. Improvements in spectacles and hand-frames.

2772. W. Clark, 53, Chancery-lane, engineer. An improvement in sewing machines. (A communication.)

2773. G. S. Melland, Lime-street, City, gun manufacturer. Improvements in breech-loading firearms and ordnance. (A communication.)

2775. A. Barclay and A. Morton, engineers, Kilmarnock. Improvements in certain apparatus for injecting and ejecting fluids.

2778. M. Mellor, Nottingham, framesmith and machine builder. Improvements in machinery or apparatus for the manufacture of looped or knitted fabrics.

Dated November 9, 1863.

2781. H. Mège, 10, Rue de la Fidelité, Paris, professor of chemistry. Certain improvements in the manufacture of soap.

2782. W. J. Cunningham and H. Connop, Everett-terrace, Victoria Dock-road. Improvements in sawing machines.

2783. G. T. Bousfield, Loughborough-park, Brixton. Improvements in the construction of ships and vessels. (A communication.)

2784. N. Thompson, Abbey-gardens, St. John's-wood. Improvements in apparatus for stopping bottles and other vessels.

2785. G. Ryder, Church Gate Engine Works, and M. Gutteridge, East-street, Leicester. Improvements in hay-making machines.

Dated November 10, 1863.

2787. T. Weston, 5, Montague-street, Dublin. Improvements in printing presses.

2788. J. C. Habicht, 4, South-street, Finsbury, merchant. Certain improvements in keyless watches. (A communication.)

2789. G. Yates, Wolverhampton, mechanic. Improvements in machinery to be used in the manufacture of heel tips and toe tips, and toe plates for boots and shoes.

2790. J. Ramsbottom, Accrington, Lancashire, engineer. Improvements in machinery or apparatus for measuring and registering fluids, and in obtaining motive power from the same.

2791. S. J. Bartlett, Maidstone, watch and clock maker. Improvements in taps.

2792. H. A. Bonneville, 24, Rue du Mont Thabor, Paris. An improved cowl or chimney pot. (A communication.)

2793. F. Castelnau, Villefranche, Haute Garonne, France. Improvements in the construction of two-wheeled vehicles or carriages.

2794. J. Mash, Bowden, Cheshire, engineer. Improvements applicable to safety valves and pressure or temperature gauges.

2795. S. Faulkner, Blackley, Lancashire, cotton spinner, J. Berry, Newton Heath, Lancashire, gentleman, and G. Harrison, Blackley, mechanic. Improvements in apparatus for grinding cards used in carding engines.

2796. S. Faulkner, Blackley, Lancashire, cotton spinner. Improvements in carding engines.

2797. J. Cutler, Gloucester-road, Upper Holloway. Improvements in the construction of ornamental fountains.

Dated November 11, 1863.

2801. T. M. Reade, Liverpool, architect, and J. Hewitt, Stanley, near Liverpool, plumber. Improvements in the apparatus for regulating and controlling the supply of water to water-closets and other purposes.

2802. J. Fottrell, Liverpool, merchant and warehouse owner. Improvements in deodorizing petroleum and other mineral oils.

2803. D. Dawson, Milnsbridge Chemical Works, Huddersfield. Improvements in the production of colours for dyeing.

2805. H. Melton, Regent-street, hatter to the Royal family. Improvements in shakos, military and other hats and caps.

2807. M. Stainton, South Shields, iron founder, and D. Lawson, South Shields, pattern-maker. Improvements in apparatus for steering ships and vessels.

2808. W. Clissold, Dudbridge Works, near Stroud, engineer. Improvements applicable to machinery for opening, cleaning, preparing, and carding wool and other fibrous substances.

2809. G. Haseltine, 12, Southampton-buildings, Chancery-lane, civil engineer. Improvements in endless chain horse powers. (A communication.)

PATENTS APPLIED FOR WITH COMPLETE SPECIFICATIONS.

Dated November 11, 1863.

2806. W. D. Richards, Boston, United States. Improvements in caloric or heated air engines. (A communication.)

Dated November 12, 1863.

2818. E. Rowland, Manchester, engineer. Certain improvements in apparatus for weighing solid bodies, and for measuring fluids, parts of which improvements are also applicable to the opening and closing of dampers.

NOTICES OF INTENTION TO PROCEED WITH PATENTS.

From the *London Gazette*, November 24, 1863.

1740. J. Mortimer. Dwelling-houses.

2678. J. Rawlings. Attaching cords to window sashes.
2695. J. Brigham and R. Bickerton. Reaping and mowing machines.
2771. L. Braham. Spectacles and hand-frames.
2816. E. Rowland. Weighing and measuring.

The full titles of the patents in the above lists can be ascertained by referring back to their numbers in the list of provisional protections previously published.

Opposition can be entered to the granting of a patent to any of the parties in the above list who have given notice of their intention to proceed, within twenty-one days from the date of the *Gazette* in which the notice appears, by leaving at the Commissioners' office particulars in writing of the objection to the application.

LIST OF SEALED PATENTS.

Sealed November 18, 1863.

1240. E. Christmas.
1249. S. Rhodes.
1258. T. P. Salt.
1261. H. Wren and J. Hopkinson.
1268. J. Cassell.
1279. J. Fawcett.
1282. W. Snell.
1284. T. A. Blakeley.
1286. T. A. Blakeley.
1287. G. Stevens.
1290. J. Higgins and T. S. Whitworth.
1295. W. Cormack.
1297. J. S. Bickford and G. Smith.
1300. F. Potts and J. Key.
1312. G. Köttgen.
1313. H. B. Girard.
1315. J. Hilliar.
1330. A. Bastow.
1399. F. A. Calvert.
1403. T. Gray.
1405. W. Clark.
1413. W. C. Brocklehurst, J. Creighton, C. Makinson, and J. Creighton.
1422. R. C. Furley.
1448. M. Hatschek.
1539. J. Watts.
1692. G. Haseltine.
1762. W. Wood.
1998. C. C. Dennett.
2152. A. V. Newton.
2205. J. C. Lott.
2223. N. Thompson.
2314. I. de Angelis.

Sealed November 20, 1863.

1292. J. Sturgeon.
1301. R. A. Brooman.
1303. R. A. Brooman.
1304. F. Kingsbury.
1305. G. Smith.
1311. E. Hunt.
1322. J. Munro and R. Scott.
1365. W. Clark.
1880. H. A. Bonneville.

Sealed November 24, 1863.

THE
MECHANICS' MAGAZINE.

LONDON, FRIDAY, DECEMBER 4, 1863.

BOILER INSPECTION.

It would prove anything but an uninteresting task to collect all that has been written on the subject of boiler explosions from Savary's time to the present. Such a compilation, especially if illustrated with drawings of all the mechanical arrangements proposed for their prevention, could not fail to prove attractive, perhaps useful. The work would be vast; yet this characteristic would but prove how ardently men have sought, by every conceivable adaptation of machinery, to prevent the recurrence of the frightful calamities which have invariably attended the employment of steam power. The want of an efficient safety apparatus has, indeed, been always the prominent idea in the minds of those who have turned their attention to the subject. Ingenious men, in every nation where steam power is employed, have still sought safety on the same general principles. It is apparently a matter of no moment, that these principles have been proved fallacious by the experience of a century. Precisely the same things are patented over and over again, pushed into notoriety, used largely, and praised for the time being; yet the journals of each day contain a record of catastrophes which such schemes, however ingenious, have proved utterly powerless to prevent. We do not suppose there is a boiler at work this week in the kingdom which is not provided with safety valves, lead plugs, floats, or possibly some other arrangements which ought to render an explosion impossible. Yet, before many days have lapsed, it is a matter of certainty that one or more of them will have exploded, carrying death and destruction into the centre of busy communities. This fact is so pregnant, so full of instruction, and so generally recognized as a proved thing, that it is remarkable in the extreme that all interested have not investigated the question in a more extended spirit. It seems strange that the sudden destruction of a steam generator should still be attributed either to something occult and mysterious, or to a cause which could not operate while the safety apparatus provided performs its assigned duty. It is patent to the most superficial, that the hosts of safety apppliances which have been fitted to boilers, for years back, have failed to reduce the number of explosions in any appreciable degree. Why this should be the case, we would have thought an interesting question; nevertheless it is generally passed over; and instruments which we have no doubt are capable of doing their duty in the most perfect manner, receive nothing but reproach and contumely should a steam generator to which they are fitted, unluckily chance to explode. If a jury try such a case, the gentlemen composing it usually consider the catastrophe as the result of an over—that is an exceptional—pressure of steam, or shortness of water. It is a matter of no consequence that witness after witness may prove that the gauges showed an abundance of water the minute before the event, and that the safety valve was in perfect order. Juries, in too many instances, refuse to believe the testimony afforded them by either gauges or witnesses, and come to the conclusion that the former must have been out of order and fallacious, or that the latter are interested, not very conscientious, and therefore not very trustworthy. Hence, in many instances, the accident is ascribed to causes which had nothing whatever to do with it, solely because the simple fact is overlooked, that no safety apparatus, of any kind, or however perfect, can do more than provide for certain exceptional contingencies, and that, until these contingencies do occur, they must remain utterly inoperative for good or for evil. When we reflect that all evidence goes to show in the most positive manner that explosions usually take place under the ordinary conditions of daily working, it is no longer difficult to understand how futile must be the attempt to check what has become a national evil by any improvements in mechanical appliances alone.

An explosion can only be the result of an over-pressure of steam, the weakness of the boiler plates, or of some mysterious phenomena for which we cannot account. We have not alluded to shortness of water as a cause, because that is already included under the head of want of strength in the generator; for almost the only way in which a red-hot plate can operate in causing, or rather permitting, an explosion, is by giving way. It is just possible, that in the case of some generators with a large heating surface and confined steam room, a red-hot plate might produce steam enough, on the influx of water, to overcome the resistance of the plates, nevertheless, this is very unlikely. In 1832-3, the members of the Franklin Institute made a series of elaborate experiments on steam, in the States. Among others, they heated a small boiler red-hot and pumped cold water into it, the result was not an explosion; the boiler leaked at all the seams, in consequence of the contraction of the plates; and it was found impossible to raise more than a few pounds of pressure in this way. This is pretty conclusive evidence against the red-hot-plate theory. As to the mystical one, we cannot help regarding it as an absurdity, unworthy of being entertained by any one pretending to scientific acquirements. As it is, it can only be applicable to the *violence* of an explosion, a subject which we have treated of at length from time to time. Just now, we do not wish to deal with the so-called mysterious, but with the evident; and, in pursuit of this intention, we assert that the great-bulk of evidence goes to show that immeasurably the larger proportion of the vast number of explosions, which spread misery through our mining and manufacturing districts, are the result of negligence and (shall we add?) parsimony. We admit that, in a very few exceptional cases, explosions do occur from causes which are unknown, or at least, not readily discoverable; but such instances are so rare, that they may be regarded as little more than phenomena—interesting, it is true, to the scientific man as problems in natural philosophy, but from their great rarity influencing the question in a social point of view, very little, if at all. It is to be regretted, that from the interest these have excited, attention has been, to a great degree, called away from the consideration of cases where the causes have been patent—cases which appear to increase rather than diminish in the frequency of their recurrence. Were it possible for us to become acquainted with the actual events in the history of the thousands of steam boilers in daily use, we believe that all amazement at an explosion, and speculation as to its cause, would be exchanged for a feeling of surprise that these catastrophes do not take place more frequently. We have attributed explosions to parsimony and negligence; we may be accused of writing harshly; we care not, so long as we write truly. These events bear the same relation to the faculty of engineers, that cholera and consumption do to the faculty of medicine. Their constant recurrence, is either a disgrace to the science of the age, or else, as is really the case, it shows that the evil is one which science alone is powerless to redress. If remediable, as we believe it to be, it certainly is not so by mere scientific discussion. It has become a social evil—an evil deeply concerning the many; and it is to the consideration of the question in this light, that we would urge, not only the engineer, but the public at large.

Were there no such thing as corrosion, boilers would probably last almost indefinitely, and explosions would be few and far between. As it is, their duration depends on many circumstances, scarcely so well understood as they should be. Destructive influences often operate with extreme and unaccountable rapidity. Plates perfectly sound to-day may be almost eaten through in the course of a very few months; and there is no means whatever of ascertaining the true state of affairs, save by frequently repeated, and careful inspection. In this system lies the true source of safety. It alone defines the true source of danger, and dictates the proper preventive measures which are required to avoid a catastrophe. No mechanism, however ingenious, can afford daily information of the exact state of the plates which form a boiler; and mechanical expedients cannot, by possibility, provide for the consequences of that deterioration to which they are exposed from the first moment a boiler is set to work. Because an iron tube, exposed to an intense heat, will bear a certain pressure when new, or even when much worn, that is no reason that it should always do so.

Our pages contain the monthly reports of the Manchester Boiler Association—they are fearfully suggestive. That for the recent month, contains a record of no fewer than 106 defective boilers, out of 381 examined; 14 of the defects being of the gravest character, and likely to lead to the most disastrous results. "An illustration," says Mr. Fletcher, "has lately been met with, of the importance of removing portions of mid-feather walls, in order to give an opportunity of examining the plates. On this being done, at the instance of the Association, in the case of a boiler lately put under its care, the bottom, although *presumed by its owner and engineer to be perfectly sound, was found to be nearly eaten through by corrosion, and on the very point of explosion.*" Such a fact as this is not a mere isolated example of what may take place. It is an illustration of what is daily going on; and it points out, in the most powerful light, the absolute necessity for a united organization all over the kingdom, to carry out, in the most perfect manner, those principles of inspection inaugurated by the Manchester men. "Six explosions," writes Mr. Fletcher, "have occurred during the last month, resulting in the death of eleven persons and the injury of eighteen others—*not one of the boilers in question was under the inspection of the Association.*" Nearly every report contains the same announcement of an almost perfect immunity from danger, following on the labours of the Committee of Inspection. It becomes criminal any longer to shut our eyes to such facts, and refuse to accept the means of safety placed at our disposal.

No one who has not resided for a lengthened period in our mining and manufacturing districts, can conceive of the reckless disregard of human life displayed in the employment of steam power. Boilers are patched in the rudest manner while they will hold together. We have seen a plain cylindrical boiler of 4 ft. in diameter and some 30 ft. long, carrying 60 lbs. steam, with three patches over the fur-

nace side walls, each consisting of a plate more than a square foot in area, covering a rent, the result of corrosion. These patches were not rivetted on. Each was fixed in its place by a single ¾ in. bolt, tapped into a flat bar 2½ in. by ½ in. and a couple of feet long, placed outside the shell, the plate being placed inside and held up to its place by the pressure of the steam, the joint being made tight (?) by red-lead and a bit of canvas. This kind of patch is common all through Staffordshire, and is used because the plates will not bear rivetting from wear. We have seen the boiler-maker, ere now, send his hammer through the so-called sound plate, by accidentally striking it, instead of the rivet, which he wished to close. We might accumulate a volume of such instances were it necessary.

Those who employ steam power should recollect that the duration of a boiler is far from being a mere question of time. It depends on so many circumstances that it is impossible to say what may be its condition without frequent and careful inspection by those who can form a proper opinion; and we may conclude this article by pointing out that every man who makes use of steam power, is guilty of criminal negligence if he disregards the means of safety which inspection alone can place ready to his hand.

THE ORDNANCE REPORT, 1863, CONDENSED; AND CONCLUSIONS FROM IT.

No. IV.

THE MERSEY STEEL AND IRON COMPANY.

SUPPLEMENTARY to part No. III., which incontestably proves the discouragement every competitor of the Elswick Company has encountered at the War-office, the case of the Mersey Steel and Iron Company stands conspicuous and deserves especial notice.

The celebrated Horsfall gun was manufactured by the last-named company in 1854. It was first tried on the sands near Liverpool. The result was so remarkable, proving the great range and power of the gun, that the manufacturers, in a truly patriotic spirit, presented the piece, which had cost many thousand pounds, to the British Government. It was shipped in the Mersey and delivered to the Ordnance Department. Some time afterwards it was fired on the beach near Portsmouth, with results which again proved its immense range and ought to have fixed the attention of the War-office on its capabilities. But no notice was taken of these experiments for some time after, until, in 1862, in consequence of the subject being mentioned in the House of Commons, and on the complaint of the constructors, that their gun had not been submitted to fair a trial in competition with the Armstrong gun, it was transported to Shoeburyness, where it was fired with extraordinary success, sending its missile through and through the "Warrior" target, as if the structure had been a bandbox. It caused apalling destruction to the armour and frame of the ship, making a ragged aperture 2 ft. to 3 ft. square. Two or three such smashing shots below the water-line would have sunk the "Warrior." The event created a sensation at the time; and it was thought the natural result would be an order, from the War Department to the Mersey Company, for the construction of another gun of the same calibre, with improvements, which the company was prepared to introduce, with a diminution in the weight. But no encouragement was held out to them. The opportunity, which has always been afforded to Sir W. Armstrong and his company, to make new trials and remedy defects revealed by experiments, at the Governmens expense, was withheld from the liberal constructors of the Horsfall gun. Their legitimate expectations were disappointed.

The occasion, however, was not lost to the Elswick Company, which was supported as usual by the War Department. If the Mersey could produce a 13-in. wrought-iron gun, why should not Elswick equal or surpass it? With the Government sanction, whilst the former company received the cold shoulder, the latter proceeded to make the so-called 600-pounder, which was tried at Shoeburyness, the 19th November last. This gun had a fair trial, which is more than can be said of the Mersey gun. The latter was fired four or five times, as if reluctantly, and the results were reported in the *Times* in a disparaging tone. With the Armstrong great gun, sixteen rounds were fired at different elevations; a whole day was devoted to the experiments, which the *Times* reporter, inspired no doubt by the War-office, recorded with great precision and in exaggerated terms of panegyric.

The Mersey monster, however, was substantially as great a success as the Armstrong monster, which, although called a 600-pounder, is really only a 300-pounder, being within the fraction of an inch, of the same calibre as the former, so that both guns are of the same power and calculated to fire solid round shot, or elongated projectiles, of the same weight with the same charges.

This is another instance of flagrant injustice to a competitor of the Elswick Company. If that eminent and enterprising firm, the Mersey Company, had had the same favour as the Elswick Company, profiting by experience, they would doubtless have produced a gun reduced in weight, and far superior to their first essay, which might have successfully rivalled the great Armstrong shunt. At all events justice has not been done to them.

In the Appendix to the Ordnance Report, pp. 368—370, we find War-office reports which place the conduct of that Department to the Mersey Company in a very doubtful light. In December, 1860, the Company delivered to the War-office two blocks of their solid forged metal, for the purpose of being tested in comparison with Armstrong coils. "The two blocks were manufactured, at the Royal Gun Factory, into a 12-pounder and a 40-pounder gun, bored, turned, and fitted exactly in accordance with those two classes of Armstrong guns." These Mersey guns were subjected to the severest endurance, proofs similar to those by which the Armstrong guns are tested. The Ordnance Select Committee, in September, 1862, at the conclusion of the experiments, reported to the Secretary of State, "that they consider that both these guns have shown an endurance, if not fully equal to that of guns made on the coil system, yet at least ample for the requirements of the service;" and "the Committee request to be furnished with particulars of cost, that they may be in a position to form an opinion whether it is worth while, with a view to ultimate economy of manufacture, to test more Mersey Company's guns."

The required information having been furnished, shows "that the cost of the Mersey steel guns is £185 for the 40-pounder, and £75 for the 12-pounder, against £249 and £90 respectively for the Armstrong coil-guns, being a saving of £64 on the 40-pounder, and £15 on the 12-pounder gun." These differences are equal to a reduction of 25 and 16 per cent. on the pieces—an enormous reduction when reckoned upon the millions expended on Armstrong ordnance.

The Report of the Ordnance Select Committee concludes by "recommending the War-office to call upon the Mersey Company to supply three 40-pounder blocks and three 12-pounder blocks, similar to those previously furnished, in order that they may be bored, rifled, and finished in the Royal Gun Factory for further experiments."

It appears that the heads of the War Department gave no effect to this honest and economical recommendation. The Mersey Company were left in ignorance of the success which had attended the first trial by the Government of their metal in solid forgings, until the Report we are reviewing was printed by order of the House of Commons. No wonder that the gentlemen, who compose the Mersey firm, like so many others, who imagined they could obtain a fair trial from the War-office, withdrew from competition in perfect disgust, when they found it useless to contend against Armstrong influence in high quarters.

THE ARMSTRONG SYSTEM.

The country has paid nearly three millions sterling for the reconstruction of its artillery; three million is a large sum, and the country has a right to know what it has got for its money. We would gladly lend our aid to afford that valuable information, but we cannot. In vain have we searched through the seven hundred folio pages of the Report; we can nowhere discover value received for the sum expended, beyond the guns and projectiles delivered into the national arsenals. If these munitions of war should prove to be worthless, there will be nothing to represent the money spent. We do not affirm that that will prove to be the case; the Report shows that opinions are divided on the subject; and with some share of fairness, it may be said, that the value of the Armstrong ordnance yet remains to be proved, by the test of actual warfare. So far as we at present know anything positive from that, the only reliable field of experience, the evidence is inconclusive. The reports on the practice with the field batteries in China are conflicting. On one occasion, in the attempt to breach the Taku Forts, smooth-bore guns were brought up to do the work which the rifled Armstrongs failed to accomplish. Naval officers are nearly unanimous in condemning the heavy Armstrongs as broadside guns. The experiments against armour plates have proved that, for penetration, the 100-pounder Armstrong is inferior to the cast-iron 68-pounder; the First Lord of the Admiralty has given evidence to that effect in the following words:—"For naval purposes, at 200 yards, our old 68-pounder is a more powerful gun than the 100-pounder Armstrong gun."

Bnt still we are assnred by the Armstrong party, of which the *Times* is the exponent, that the country is in possession of an equivalent for its large expenditure, in the valuable acquisition of the "Armstrong system."

We have diligently sought by the light of the compendious evidence in the Report we are analyzing, to ascertain what that "system" is: but we have been baffled; and our only consolation is, that the Select Committee on Ordnace, at the conclusion of their arduous labours, found themselves in the same predicament. They do not venture to affirm what the system is; but summing up the pregnant question, they introduce the following paragraph in their Report:—"The combination of construction (coils of iron welded together, formed into hoops shrunk one over another), breech-loading, rifling, and coating the projectiles with soft metal, *came to be viewed* as the Armstrong system." In the proceedings of the Committee, it is reported, that the question "that those words be inserted," being

put, the resolution was unanimously agreed to. This proves that the most strenuous supporters of Sir William Armstrong amongst the members of the Committee, and they were not few in number, were unable to give a more definite expression to their conception of his "system."

So numerous are the facts, so contradictory are the opinions and authorities on both sides, that it is no wonder the Committee declined pledging themselves to any decisive definition of the Armstrong system. Even Colonel St. George and Captain Jarvis, and other War-office officials, including General Peel himself, would not venture to decide the question.

There was one way of setting it at rest, the production of the specifications of the Armstrong patents; but fruitless were the endeavours of the independent members of the Committee to obtain an inspection of those documents. The earnest attempts of some of them to get at the real nature of the "system" from the descriptions in the specifications, which would have settled the point, were defeated by a peremptory refusal on the part of the Government to produce them.

The question of the Armstrong system is in so vague and unsatisfactory a condition, it is difficult to deal with it summarily. In our next number we propose to show that, in the general description of the so-called system, and in its details, as explained by the evidence, there is no novelty of idea, no invention of Sir W. Armstrong, and no method of construction, or process of manufacture, which was not previously practised or known to other ordnance engineers, and which could not have been carried into execution more effectively, more promptly, and more economically by many other manufacturers, if the Government had afforded them the opportunity of competing on equal terms with the Elswick Company.

(To be continued.)

INDUSTRIAL BIOGRAPHY.*

Who has not read Mr. Smiles' "Lives of the Engineers"? Pleasant volumes, abounding in quaint strange stories of life struggles, of battles fought and won by mind over stern matter, aye, and more difficult task, over the opposing intellects of men, often envious, and always sceptical. Mr. Smiles has established a world-wide reputation as the champion of the engineer and the inventor. What matter, that he sometimes acts the part of knight-errant, and couches his lance in defence of those who have no claim on his services, simply because they appear to enjoy scant justice at the hands of others? His books are none the less readable, that he throws the halo of a fine imagination around the acts of his heroes, investing them with a simplicity of purpose, a nobleness of heart, which is all too rare in the world. With the memory of his last book before us, need we say that we welcome yet another wrought by the same brain. "Industrial Biography" is a happy title; and Mr. Smiles tells us, in a few phrases, how it is that he came to give the volume to the world. While preparing the "Lives of the Engineers," the industrious searcher through the records of the past, frequently came across the tracks of celebrated inventors, mechanics, and iron-workers—the founders in a great measure of the modern industry of Britain, whose labours seemed to him well worthy of being traced out and put on record, and the more so, that their lives presented many points of curious and original interest. Our author hardly does himself justice in stating that his principal task has lain in selecting and arranging the materials placed at his disposal, supplied, for the most part, by the descendants or surviving contemporaries of the men whose leading characteristics he records. The volume before us bears little evidence of the heterogeneous mass of papers from which it has been built up with a prudent and skilful hand. Traces of the original material, it is true, start out here and there in bold relief, through its pages; but they only serve to impart a quaint tone of truthful simplicity to the whole, which is very pleasing. Thus, in the first chapter, which treats of "Iron and Civilization," in alluding to the scarcity of iron, he writes:—

To supply themselves with swords and spear-heads, they (the Scots under Wallace) imported steel from Flanders, and the rest they obtained by marauding incursions into England. The district of Furness, in Lancashire—then, as now, an iron producing district—was frequently ravaged with that object, and, on such occasions, the Scots seized and carried off all the manufactured iron they could find, preferring it, though so heavy, to every other kind of plunder. About the same period, however, iron must have been regarded as almost a precious metal in England itself; for we find that in Edward III.'s reign, the pots, spits, and frying-pans of the Royal kitchen were classed among his Majesty's jewels.

The same famine of iron prevailed to a still greater extent in the Highlands, where it was even more valued, as the clans lived chiefly by hunting, and were in an almost constant state of feud; hence, the smith was a man of almost indispensable importance among the Highlanders; and the possession of a skilful armourer was greatly valued by the chiefs. The story is told of some delinquency having been committed by a Highland smith, on whom justice must be done; but, as the chief could not dispense with his smith, he generously offered to hang two weavers in his stead!

We may point out the chapter on Andrew Yarranton as affording a peculiar example of this style.

It is to be wished that Mr. Smiles had possessed a more thorough knowledge of engineering than he does. In the biography of men he is at home, successful, and as a consequence, charming, but in the biography of a machine or a tool, he is usually inaccurate, loose in his style, and scarcely perspicuous. We cannot have everything, however, and are well enough content with the food for thought which Mr. Smiles supplies. In some of his sketches of character, he is peculiarly happy: witness the following of the late Henry Maudslay:—

Like every good workman who takes pride in his craft, he kept his tools in first-rate order, clean and tidily arranged, so that he could lay his hand upon the thing he wanted at once, without loss of time. They are still preserved in the state in which he left them, and strikingly illustrates his love of order, "nattiness," and dexterity. Mr. Nasmyth says of him, that you could see the man's character in whatever work he turned out, and as the connoisseur in art will exclaim at sight of a pictnre, "That is Turner," or that is "Stansfield," detecting the hand of the master in it, so the experienced mechanician, at sight of one of his machines or engines, will be equally ready to exclaim, "That is Maudslay;" for the characteristic style of the master mind is as clear to the experienced eye in the finished machine as the touches of the artist's pencil are in the case of the finished picture. Every mechanical contrivance that became the subject of his study, came forth from his hand and mind rearranged, simplified, and made new, with the impress of his individuality stamped upon it. He at once stripped the subject of all unnecessary complications, for he professed a wonderful facility of *knowing what to do without*—the result of his clearness of insight into mechanical adaptations, and the accurate and well defined notions he had formed of the precise object to be accomplished. "**Every member or separate machine in the system of block machinery,**" says Mr. Nasmyth, "**is full of Maudslay's presence. And in that machinery, a constructed by him, is to be found the parent of every engineering tool, by the aid of which we are now achieving such great things in mechanical construction. To the tools, of which Maudslay furnished the prototypes, are we mainly indebted for the perfection of our textile machinery, our locomotives, our marine engines, and the various implements of art, of agriculture, and of war. If any one who can enter into the details of this subject will be at the pains to analyze, if I may so term it, the machinery of our modern engineering workshops, he will find in all of them the strongly marked feature of Maudslay's parent machine, the slide rest and slide system—whether it be a planing machine, a slotting machine, a slide lathe, or any other of the wonderful tools which are now enabling us to accomplish so much in mechanism.**"

The same tone pervades the whole book. Mr. Smiles treats of men who have risen to fame by a life-long struggle, indomitable energy, and a thorough reliance on their own powers. To write the biography of men like Dud Dudley, Andrew Yarranton, Henry Cort, or Joseph Clement, must constitute a pleasure in itself; while to read it, as Mr. Smiles has put it before us, conveys a feeling of something more than pleasure. To do full justice to the book in a short article, is beyond our power; the public must read and enjoy for themselves. We append one quotation more, the utmost that our limits will allow, and we must add a word of praise for the cheap and unpretending form in which such a charming book is laid before the public:—

The excellence of Mr. Clement's tools, and his well-known skill in designing and executing work requiring unusual accuracy and finish, led to his being employed by Mr. Babbage to make his celebrated Calculating or Difference Engine. The contrivance of a machine that should work out complicated sums in arithmetic with perfect precision, was, as may readily be imagined, one of the most difficult feats of the mechanical intellect. To do this was in an especial sense to stamp matter with the impress of mind, and render it subservient to the highest thinking faculty. Attempts had been made at an early period to perform arithmetical calculations by mechanical aids more rapidly and precisely than it was possible to do by the operations of the individual mind. The preparation of arithmetical tables of high numbers involved a vast deal of labour, and even with the greatest care errors were unavoidable and numerous. Thus in a multiplication-table prepared by a man so eminent as Dr. Hutton for the Board of Longitude, no fewer than forty errors were discovered in a single page taken at random. In the tables of the "Nautical Almanac," where the greatest possible precision was desirable and necessary, more than five hundred errors were detected by one person; and the Tables of the Board of Longitude were found equally incorrect. But such errors were impossible to be avoided so long as the ordinary modes of calculating, transcribing, and printing continued in use.

The earliest and simplest form of calculating apparatus was that employed by the schoolboys of ancient Greece, called the Abacus; consisting of a smooth board with a narrow rim, on which they were taught to compute by means of progressive rows of pebbles, bits of bone or ivory, or pieces of silver coin, used as counters. The same board, strewn over with sand, was used for teaching the rudiments of writing and the principles of geometry. The Romans subsequently adopted the Abacus, dividing it by means of perpendicular lines or bars, and from the designation of calculus which they gave to each pebble or counter employed on the board, we have derived our English word to *calculate*. The same instrument continued to be employed during the Middle Ages, and the table used by the English Court of Exchequer was but a modified form of the Greek Abacus, the chequered lines across it giving the designation to the Court, which still survives. Tallies, from the French word *tailler*, to cut, were another of the mechanical methods employed to record computations, though in a very rude way. Step by step improvements were made; the most important being that invented by Napier of Merchiston, the inventor of logarithms, commonly called *Napier's bones*, consisting of a number of rods divided into ten equal squares and numbered, so that the whole when placed

* "Industrial Biography: Iron-workers and Tool-makers." By Samuel Smiles. London: John Murray, 1863.

together formed the common multiplication table. By these means various operations in multiplication and division were performed. Sir Samuel Morland, Gunter, and Lamb introduced other contrivances, applicable to trigonometry; Gunter's scale being still in common use. The calculating machines of Gersten and Pascal were of a different kind, working out arithmetical calculations by means of trains of wheels and other arrangements; and that contrived by Lord Stanhope for the purpose of verifying his calculations with respect to the National Debt was of like character. But none of these will bear for a moment to be compared with the machine designed by Mr. Babbage for performing arithmetical calculations and mathematical analyses, as well as for recording the calculations when made, thereby getting rid entirely of individual error in the operations of calculation, transcription, and printing.

The French Government, in their desire to promote the extension of the decimal system, had ordered the construction of logarithmical tables of vast extent; but the great labour and expense involved in the undertaking prevented the design from being carried out. It was reserved for Mr. Babbage to develop the idea by means of a machine which he called the Difference Engine. This machine is of so complicated a character that it would be impossible for us to give any intelligible description of it in words. Although Dr. Lardner was unrivalled in the art of describing mechanism, he occupied 25 pages of the *Edinburgh Review* (vol. 59) in endeavouring to describe its action, and there were several features in it which he gave up as hopeless. Some parts of the apparatus and modes of action are indeed extraordinary—and perhaps none more so than that for ensuring accuracy in the calculated results—the machine actually correcting itself, and rubbing itself back into accuracy, when the disposition to err occurs, by the friction of the adjacent machinery! When an error is made, the wheels become locked and refuse to proceed; thus the machine must go rightly or not at all—an arrangement as nearly resembling volition as anything that brass and steel are likely to accomplish.

This intricate subject was taken up by Mr. Babbage in 1821, when he undertook to superintend for the British Government the construction of a machine for calculating and printing mathematical and astronomical tables. The model first constructed to illustrate the nature of his invention produced figures at the rate of 44 a minute. In 1823 the Royal Society was requested to report upon the invention, and after full inquiry the committee recommended it as one highly deserving of public encouragement. A sum of £1,500 was then placed at Mr. Babbage's disposal by the Lords of the Treasury for the purpose of enabling him to perfect his invention. It was at this time that he engaged Mr. Clement as draughtsman and mechanic to embody his ideas in a working machine. Numerous tools were expressly contrived by the latter for executing the several parts, and workmen were specially educated for the purpose of using them. Some idea of the elaborate character of the drawings may be formed from the fact that those required for the calculating machinery alone—not to mention the printing machinery, which was almost equally elaborate—covered not less than four hundred square feet of surface! The cost of executing the calculating machine was of course very great, and the progress of the work was necessarily slow. The consequence was that the Government first became impatient, and then began to grumble at the expense. At the end of seven years the engineer's bills alone were found to amount to nearly £7,200, and Mr. Babbage's costs out of pocket to £7,000 more. In order to make more satisfactory progress, it was determined to remove the works to the neighbourhood of Mr. Babbage's own residence; but as Clement's claims for conducting the operations in the new premises were thought exorbitant, and as he himself considered that the work did not yield him the average profit of ordinary employment in his own trade, he eventually withdrew from the enterprise, taking with him the tools which he had constructed for executing the machine. The Government also shortly after withdrew from it, and from that time the scheme was suspended, the Calculating Engine remaining a beautiful but unfinished fragment of a great work. Though originally intended to go as far as twenty figures, it was only completed to the extent of being capable of calculating to the depth of five figures, and two orders of differences; and only a small part of the proposed printing machinery was ever made. The engine was placed in the museum of King's College in 1843, enclosed in a glass case, until the year 1862, when it was removed for a time to the Great Exhibition, where it formed perhaps the most remarkable and beautifully executed piece of mechanism—the combined result of intellectual and mechanical contrivance—in the entire collection.

Clement was on various other occasions invited to undertake work requiring extra skill, which other mechanics were unwilling or unable to execute. He was thus always full of employment, never being under the necessity of canvassing for customers. He was almost constantly in his workshop, in which he took great pride. His dwelling was over the office in the yard, and it was with difficulty he could be induced to leave the premises. On one occasion Mr. Brunel, of the Great Western Railway, called upon him to ask if he could supply him with a superior steam-whistle for his locomotives, the whistles which they were using giving forth very little sound. Clement examined the specimen brought by Brunel, and pronounced it to be "mere tallow-chandler's work." He undertook to supply a proper article, and after his usual fashion he proceeded to contrive a machine or tool for the express purpose of making steam-whistles. They were made and supplied, and when mounted on the locomotive the effect was indeed "screaming." They were heard miles off, and Brunel, delighted, ordered a hundred. But when the bill came in, it was found that the charge made for them was very high—as much as £40 the set. The company demurred at the price—Brunel declaring it to be six times more than the price they had before been paying. "That may be," rejoined Clement, but mine are more than six times better. You ordered a first-rate article, and you must be content to pay for it." The matter was referred to an arbitrator, who awarded the full sum claimed. Mr. Weld mentions a similar case of an order which Clement received from America to make a large screw of given dimensions "in the best possible manner," and he accordingly proceeded to make one with the greatest mathematical accuracy. But his bill amounted to some hundreds of pounds, which completely staggered the American, who did not calculate on having to pay more than £20 at the utmost for the screw. The matter was, however, referred to arbitrators, who gave their decision, as in the former case, in favour of the mechanic.

One of the last works which Clement executed as a matter of pleasure, was the building of an organ for his own use. It will be remembered that when working as a slater at Great Ashby, he had made flutes and clarionets, and now in his old age he determined to try his skill at making an organ—in his opinion the king of musical instruments. The building of it became his hobby, and his greatest delight was in superintending its progress. It cost him about two thousand pounds in labour alone, but he lived to finish it, and we have been informed that it was pronounced a very excellent instrument.

Clement was a heavy-browed man, without any polish of manner or speech; for to the last he continued to use his strong Westmoreland dialect. He was not educated in a literary sense; for he read but little, and could write with difficulty. He was eminently a mechanic, and had achieved his exquisite skill by observation, experience, and reflection. His head was a complete repertory of inventions, on which he was constantly drawing for the improvement of mechanical practice. Though he had never more than thirty workmen in his factory, they were all of the first class; and the example which Clement set before them of extreme carefulness and accuracy in execution rendered his shop one of the best schools of its time for the training of thoroughly accomplished mechanics. Mr. Clement died in 1844, in his sixty-fifth year; after which his works were carried on by Mr. Wilkinson, one of his nephews; and his planing machine still continues in useful work.

LIGHTING ENGINE-ROOMS.

We have recently had occasion to allude in our pages to the use of Trachsell's ozone gas as a means of lighting the engine-room of the "Warrior." This gas is about 28 times heavier than the atmosphere, and it therefore becomes necessary to carry it to the burner by means of a current of air. This is obtained by a double india-rubber bellows or blower, worked by a weight and geared wheels, which carries a current equal to 12·33 cubic feet per hour, or 148 cubic feet in twelve hours, absorbing 307·469 cubic inches of ozone—equal to 1·102 gallons for fifteen lights for twelve hours—each light being equal to that of three composite candles, at eight to the pound. The cost of lighting the engine-room and screw alley with fifteen of the ozone lights for twelve hours is 4s. 5d., against 17s. 4d. for 33 oil and candle lamps, the ozone gas giving 11 per cent. more light.

M. l'Abbé Moigno transferred the paragraph which we have already inserted, to the pages of his able journal, *Le Monde*, appending the following remarks:—"Our readers will recognise in this apparatus, the gas lamp of M. Mille, with an exception altogether in favour of our clever friend. M. Mille uses neither an air-pump nor falling weight, nor any machinery whose motion is necessary to the maintenance of light. He has, in fact, brought his invention to a remarkable degree of perfection, combining simplicity with perfect efficiency. We shall shortly place before our readers details of a simple tin apparatus, installed within our library, which at the expense of 1½ kilogramme of paraffine, supplies us for twenty hours with a light far more intense than that afforded by a very large moderator lamp, usually consuming 50 grammes of oil per hour. Atmospheric air, simply by its natural tendency to diffusion, freely enters the apparatus and takes up, at all temperatures, those constituents which are necessary to convert it into a gas of far better quality than that ordinarily employed for the purposes of illumination; the light possessing a a red rather than a blue tinge. The simplicity of the arrangements has led to general admiration; and it seems certain that, ere long, this system of illumination will be universally adopted. It is eminently economical. The heaviest class of petroleum oils will not rise freely in the wick, and, being consequently burned with difficulty, are comparatively worthless: on M. Mille's system, however, they can be converted into illuminating gas at any temperature, without the use of retorts, tubing, gasometers, &c."

All this appears very interesting. *Le Monde* is an authority on such subjects; and we shall take care to place a description of M. Mille's lamp before our readers at the earliest possible moment.

TRACTION ENGINES AT WOOLWICH.

The following is an Admiralty return recently transmitted from Woolwich in reference to the traction-engine:—"The engine has been at work in Woolwich dockyard during the past twelvemonth, having been working continuously all the time, sometimes night as well as day. The machine is now in as good repair as when it was delivered. The cost of working, including maintenance and repairs, is under 20s. per day, while the work done is equal to one team of horses and twenty-five labourers. Since the engine has been employed in the yard two teams of horses have been disposed of with a view to economy." We trust that the day is not distant when the locomotive will take a prominent place in the highway and byeway traffic of the nation. It is most desirable that such facts as the above should be placed before the public in an accurate form, by those who employ this class of machinery or feel interested in its success.

NEW PUMPING MACHINERY.

We hope soon to be enabled to place before our readers a detailed description of a remarkable system of pumping recently invented by a French engineer, M. Beaumont, and spoken of in high terms by the Continental scientific press; the gentlemen connected with which inform us, in very plain terms, that the new machine will inaugurate an era in the practice of raising water in large quantities, and that it is like nothing which has gone before either in its general arrangements or its powers. All this must be received with a proper amount of caution. We know little or nothing about the machine at present, except that it consists of a series of horizontal superimposed revolving cylinders, provided with a peculiar arrangement of cells, near or at their circumference, and so arranged that the water raised by the lower cylinder is poured into that next above it; the process being repeated until it arrives at the reservoir to be filled.

An experimental apparatus has been constructed and set to work both at Strasbourg and Mulhouse, in the presence of nearly all the resident members of the Société Industriel. The official report has not yet reached us in a complete form; but the results obtained are stated as being extremely satisfactory; about 2,000 gallons per minute having been raised to a height of some 9 ft. by a steam engine indicating between 4 and 5-horse power.

TRIAL OF SHAND AND MASON'S STEAM FIRE-ENGINE.

Messrs. Shand and Mason have recently completed a steam fire-engine (the twenty-fifth turned out by the firm within the last few years), for the Watling-street Station of the London Fire Brigade. The principal novelties embraced in the construction of this machine are its small size and weight, 27 cwt., and an important improvement by which access can be got in a moment, to not only the foot valves of the pump, but to the bucket-plunger as well. In other respects, the engine resembles that which took the first prize in the small class at the Crystal Palace last summer.

An experimental trial took place on Saturday at Addington-square, Camberwell, on the banks of the Grand Surrey Canal. Steam was raised to 60 lbs. pressure in twelve minutes with ordinary firing. Unfortunately, there was no known standard at the spot by which either height or distance could be accurately measured. A fair estimate, may, however, be made of the power of the machine, from the pressure maintained in the air-vessel. The first jet used was one of ⅞ of an inch diameter, the pressure in air-vessel being 90 lbs. to 100 lbs. on the square inch, equivalent to at least 150 ft. of jet in vertical height; with a 1 in. jet the pressure was 80 lbs.; with 1⅛ in., 60 lbs. Steam was maintained at 100 lbs. without difficulty. The engine was, however, exposed to a more severe practical test on Monday night, when it did good service at a fire in Lamb's-passage, Chiswell-street, adjoining Whitbread's brewery, on which occasion it was at work without intermission for two hours, propelling water through nine 40 ft. lengths of hose, and a 1 in. jet, with a pressure of 60 lbs. in the air-vessel. We understand that Messrs. Shand and Mason are doing a considerable foreign trade in steam fire-engines just now.

TRIAL TRIP OF THE "ARETHUSA."

The "Arethusa," 35, screw frigate, was taken on Wednesday week from her moorings in Sheerness harbour to the measured mile off Maplin Sands, for the final trial of her machinery, previous to her being placed on commission, Captain W. K. Hall, commanding the Steam Reserve at Sheerness, having command of the vessel. Mr. John Dinnen, Inspector of Machinery from the Admiralty, was in attendance on the part of the Government; and Messrs. Matthews and Holliday were also present from the firm of Messrs. John Penn and Sons, constructors of the engines. The "Arethusa" was built as a sailing vessel at Pembroke 18 years ago, from designs by Sir W. Symonds, the then Surveyor of the Navy, but she has since been lengthened 41 ft. amidships, and converted into a screw frigate at Chatham dockyard. Her dimensions now are:—Extreme length between perpendiculars, 252 ft.; length of keel for tonnage, 217 ft.; extreme breadth, 52 ft. 8 in.; breadth for tonnage, 52 ft. 5 in.; depth of hold, 17 ft. 1 in.; and total amount of burden, 3,142 tons. The "Arethusa," together with the "Octavia" and the "Constance," vessels of a similar class, have each been fitted with machinery constructed with a view to obtain a greater amount of power at a less working cost than any yet introduced into the Navy. The "Arethusa" is fitted with a pair of expansive trunk engines with two cylinders 86½ in. in diameter, the trunk being 33 in. in diameter, and the length of stroke 42 in., with surface condensers, containing nearly 6 miles of 1-inch tubing. The boilers, four in number, with four furnaces to each, are fitted with superheating apparatus. The propeller is Griffith's patent, pitch 20 ft. to 26 ft., present pitch 23 ft. During the trial six runs were made at full boiler power. The results were an average speed of 11·043 knots an hour; the revolutions of engines 65 per minute; pressure of steam 23 lbs.; vacuum 27¼ lbs. At half boiler power only two runs were made. The results were an average speed of 8·780 knots, 52 revolutions, pressure of steam 16 lbs., vacuum 26 lbs. The circle was made at full boiler power, helm port 23½ degrees in 7 minutes 1 second, the diameter of the circle being 501 yards; with half the boiler power, helm starboard 28 deg., in 7 minutes 47 seconds, the diameter being 399 yards. The draught of water during the trial was 20 ft. 3 in. forward and 22 ft. 7 in. aft., the vessel being fully rigged, with guns on board, and in heavy sea-going trim. The day was fine and the sea smooth, with a wind from west-south-west, with a force of from 3 to 5. The trial, which occupied about six hours from the time the vessel left her moorings till her return, was satisfactory. The "Arethusa," with her sister competing vessels the "Constance" and the "Octavia," will, it is said, shortly be placed in commission.

STEAM ON CITY RAILROADS.

It is announced, in one of our contemporaries, that six "dummy" engines are building for a street railway in Philadelphia, and but a short time ago we saw mention made of another enterprising corporation that had determined to adopt steam in lieu of horse-power, and thereby save themselves and the public both time and money. It is almost useless to expect anything of our railroad authorities in this respect; notwithstanding all the examples set before them, the arguments in favour of the steam system, and the evidence of common sense, we will still have to put up with horse-power; and the only dummies in use or in existence on our street railroads seem to be those persons who direct and control the principal interests of them.

The gridiron railway, in spite of the outcry and opposition manifested towards it, is gradually extending its iron arms, and even now grasps by far the greater part of the city streets occupied by vehicles devoted to passenger traffic. We had hoped that the directors of these roads would have seen fit to try at least one of the steam cars (they are *not* "dummies"), and compare the cost of running it with that of horses in all essential points; thus to satisfy themselves by practical demonstration that steam is better than horse-power for the purpose discussed. In this we have been disappointed, and horses rule the road, to the exclusion of machinery, which is obviously cheaper than any other means of transportation.

It would be considered fatuitous and short-sighted to the last degree for any railroad company to discard all its engines, run a canal alongside the line, and put on a number of boats and horses to "accommodate freight;" yet this the street railways do, in effect, by employing horses to accomplish tasks that properly belong to machinery. Even in the absence of any positive data in black and white as regards the expense of the two systems for carrying passengers by steam or horse power, it is safe to assume that the former is the most preferable in all respects, on the general ground that the introduction of machinery inevitably enhances the profits of any trade or business, provided the same be properly carried on.

There is no occasion, however, to presuppose that railroad men are ignorant of the comparative economy of steam as opposed to horse-power, and we must seek for some other motive for their non-adoption of the first. Certainly no unprejudiced person could hesitate to declare in favour of steam; the arguments published from time to time in the *Scientific American* (which have never been refuted in the slightest particular) show conclusively that the advantage is in favour of steam. We can only await the slow dawning of intelligence and enterprise upon the minds and convictions of our railroad men; for the pressure of public opinion and the examples of the directors of street railways in other cities seem thus far to have had very little effect.—*Scientific American.*

GREAT TELESCOPE AND PHOTOGRAPHS OF THE MOON.

The American *Journal of Photography* contains a very full report of Henry Draper's Paper recently read before the American Photographical Society on his new telescope, and the large photographs which he has taken of the moon. In the Paper it is stated that, in the autumn of 1858, Dr. Draper determined to make the largest reflecting telescope in America, the construction of which, with various improvements introduced, have occupied his time up to the present period—more than five years. This telescope is nearly 16 in. in aperture and 13 ft. in focal length, and was intended to be devoted to celestial photography; consequently it has many novelties fitting it for this purpose. It has the largest silver reflector of any instrument in the world, with the exception of the one in the Imperial Observatory at Paris. A reflecting telescope is greatly superior to an achromatic one for photographic purposes. Dr. Draper first used speculum metal for his mirrors, but abandoned it at Sir John Herschel's suggestion in favour of silvered glass; the reflecting power of the latter being 93 per cent.; that of the former being but 75. The glass mirror also only weighs 16 pounds, whereas one of the same size of speculum metal weighs 138 pounds; and if the silver of the glass should accidentally be injured, it may be dissolved off by nitric acid and the mirror may be re-silvered in the course of a few hours. This may be repeated an indefinite number of times. The mirror of this telescope has cost Dr. Draper an immense amount of toil, in order to reach as nearly as possible to perfection. He ground more than one hundred mirrors of different sizes, from 19 in. to one-quarter of an inch in diameter. The mirror of this telescope is sustained in a walnut tube hooped with brass, and the frame in which it is mounted holds it at both ends, to avoid the tremulous motion so common to large instruments. When photographs of the moon are being taken, the telescope is not driven by clock-work, but is allowed to come to complete rest; the sensitive plate alone is moved in a direction and at a rate to correspond with the moon's motion. By this mode of operation, only one ounce instead of half a ton is moved. The observatory of Dr. Draper is situated at Hastings, N.Y., on a hill 250 ft. above the level of the sea. The dome which covers it is 16 ft. in diameter, supported on a point at its centre, and can be turned with a gentle pressure of the hand. This instrument can be directed to an object, shifted, and the observer himself moved to any part of the building, by a very slight exertion. A photographic laboratory is attached to the observatory. It contains all the requisite conveniences for taking photographs up to sizes of 3 ft. in diameter. One of 3 ft. and one of 2 ft. in diameter of the moon have been taken. The former represents the moon on a scale of 70 miles to the inch; the latter—2 ft. picture—is the largest that had previously been made anywhere. Celestial photography is, as yet, only in its infancy; but it is progressing rapidly.

THE IRONWORKS OF SOUTH WALES.

As an indication of the improvement which has taken place in the iron trade of South Wales, it may be mentioned that nearly all the works that came to a standstill during the depressed times of the last four years are now either in work or preparations are being made to commence operations. This gratifying state of things has been brought about by the advance in the price of iron and the good prospects of the future. Messrs. Weston and Grice, of West Bromwich, have commenced working at Cwmbran, and a considerable quantity of iron has been already turned out. The Varteg and Golynos furnaces have been blown in by Messrs. Partridge and Jones and Messrs. G. E. Bevan and Co., and part of the Llanelly works, Breconshire, has been converted into a tin-plate manufactory by Messrs. Jayne and Meadhouse. A number of first-class capitalists have also formed themselves into limited liability companies, with the view of working the Pencoed furnace, Pontnewynydd forge, and Penydarren works, together with three or four collieries. Several other smaller works are about to be resuscitated after a long standstill, and the iron trade generally shows a decided improvement as compared with what was the case twelve or eighteen months ago. Employment is plentiful, and, in fact, a scarcity of hands is felt at several of the works.

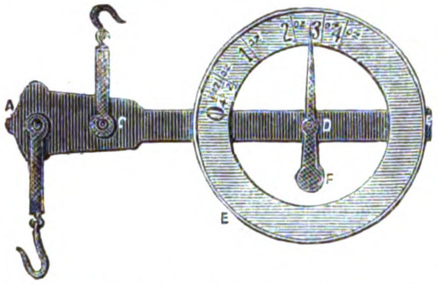
CHARING-CROSS RAILWAY.

On Tuesday, at 2 p.m., the first train passed over the Charing-cross Railway from London-bridge to the new station, now nearly completed, on the old site of Hungerford-market at Charing-cross. The train consisted of two of the heaviest new engines of the South-Eastern Railway, and a large number of carriages of different classes. Mr. Hawkshaw, the engineer of the railway, rode on the first engine, with Mr. Teuton, one of the directors; Mr. Smiles, secretary of the company; Mr. Eborall, general manager of the South-Eastern Railway Company; Mr. Wythes and Mr. Cochrane, the contractors; Mr. Ashcroft, Mr. Knight, and other South-Eastern officials. The trip proved entirely satisfactory; and after inspecting the station at Blackfriars, and the works at Charing-cross, the train returned to London-bridge. It is expected the line will be opened for public traffic in a fortnight.

HALL'S IMPROVEMENTS IN WEIGHING APPARATUS.

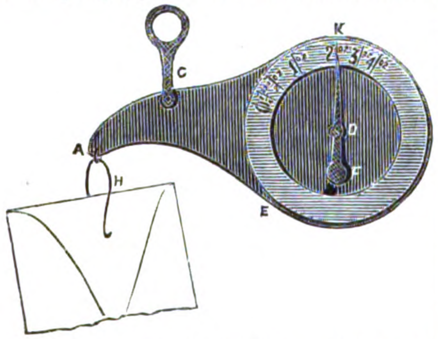
This invention, recently patented by Mr. N. R. Hall, of Rosherville, is on the principle of the common steelyard, inasmuch that the article to be weighed is suspended at the short arm of the the lever, but differs otherwise; for, instead of ascertaining the weight of an article by shifting or sliding a given weight upon the long arm until it is perfectly horizontal, the patentee allows his weighing apparatus to come to rest in any position, according as the weight of the article may draw it more or less from the horizontal line, and then discovers the weight of the article sought by means of a hand, which points to various figures representing weights, which figures are marked upon a circle, at the extremity of one end of the weighing apparatus; at the centre of this circle or dial the hand moves or plays freely upon a stationary pin, and the hand having a heavy tail end, it will always maintain a position when in use, and will therefore be directed to that number which is brought to a vertical position with the centre of the circle or dial. At the proper end for attaching the article to be weighed there is a suitable clip with hooks (or any convenient contrivance may be used for attaching the article to be weighed), and when this weighing apparatus is hung or held up for use with the article properly suspended, the circle or dial will rise more or less, and one of the numbers marked upon it will be brought to a vertical position, to which number the hand will be directed, and thereby indicate the required weight of the article.

Fig. 1 shows the common steelyard, where from A to C is the short arm of the lever or beam,



and from B to C is the long arm; but, instead of a weight shifting or sliding upon the long arm, the long arm is enlarged sufficiently to inscribe a dial of any suitably sized circle; E, a part of a circle upon it, with its centre D, at which the hand F plays freely upon a pin. This diagram is intended to set forth the application of a circle, or part of a circle, upon the long arm of the common steelyard.

Fig. 2 sets forth the general appearance of the weighing apparatus with its circle or dial E



and hand F on the pin D. The article to be weighed is seen at G, representing a letter grasped by the clip H hanging from the point A. The dial E is raised, and the vertical number indicating the weight of the letter seen at K, to which the hand F (from its construction, before described) is directed when the apparatus is hung or held up by the handle at the fulcrum C. The ... hts expressed from one quarter of an o... unces upon the circle or dial of e... drawing, do not confine or limit his invention only to those weights, for by changing the fulcrum point, or making the apparatus of various sizes, it becomes applicable to a variety of weights, which said weights can be expressed or set forth upon the circle or dial; and also for some purposes of weighing there can be numbers, letters, or words representing various charges or prices exhibited upon the circle or dial, so that articles which bear a certain scale of charges or prices according to their weight can have such charge or price readily ascertained.

BRIGHAM AND BICKERTON'S REAPING AND MOWING MACHINES.

FIG. 1

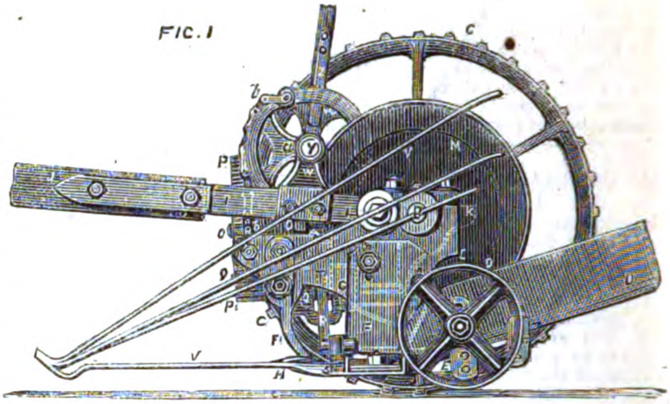


FIG. 2

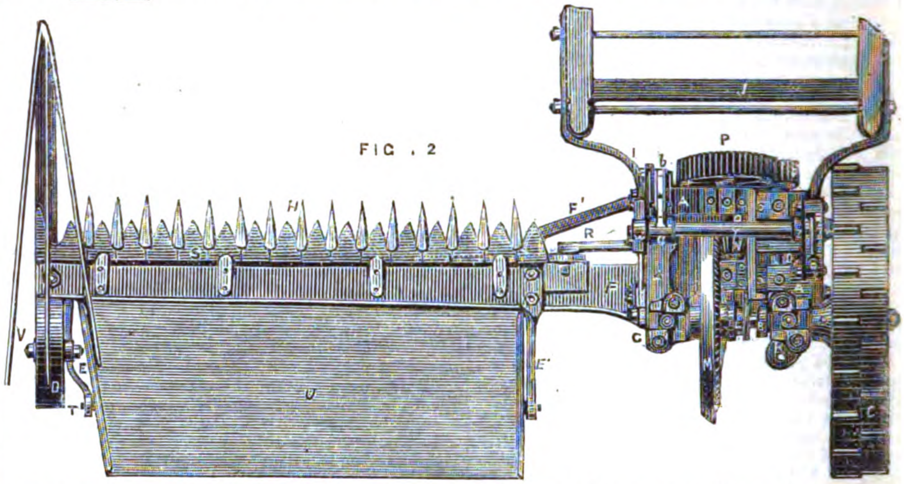


BRIGHAM AND BICKERTON'S IMPROVEMENTS IN REAPING AND MOWING MACHINES.

This invention, patented by Messrs. Brigham and Bickerton, of Berwick-on-Tweed, relates to the arrangement and construction of certain parts of machines used for reaping or mowing purposes. Under one modification or system of arrangement, the frame for receiving the main spindle and the operating gearing is cast in one piece. This frame consists mainly of a bracket piece extending across the machine, and on the upper part of which are two tubular bearings through which the main spindle passes. The outer end of this spindle projects sufficiently to admit of the bearing wheel being fitted thereto; on the other side of the machine it is supported by a small wheel carried at the outer end of the finger bar, which part of the machine is bolted to a pendent prolongation of the main frame before referred to. On the main spindle which is carried round with the motion of the driving wheel is a bevel wheel; this wheel is keyed to a short horizontal shaft, arranged longitudinally in the centre of the machine. On the forward extremity of this shaft is a spur wheel, which gives motion to a pinion on the contiguous crank shaft; this shaft is connected by a rod to the cutter bar, and communicates a rapid reciprocatory movement thereto. The cutter bar has arranged in connection with it a lever, by means of which it is readily adjusted to the required height.

Under one modification or system of arrangement of this part of the machine, a bracket-piece is affixed to the framing of the machine, and from the upper part of this bracket-piece extends an open frame of a segmental figure. There is an opening between the segmental plates of this frame to admit of the motion of the hand lever, by means of which the cutter bar is raised or lowered, and on the inner side of the outer standard of the frame a series of ratchet teeth are formed, to admit of the hand lever being fixed at any desired elevation. Through the central part of the segmental frame is passed one end of a horizontal shaft which extends across the machine, the bearings of the spindle being arranged in the frame and in a suitable bracket on the opposite side. The hand lever is keyed to the shaft before referred to, and extends outwards beyond the segmental frame to within convenient reach of the driver. On the outer side of the hand lever is fixed a blade spring, which takes into the ratchet teeth on the segmental frame, and so retains the hand lever in position. At one extremity, or other suitable part of the horizontal shaft, is keyed a segmental pulley, to which is fastened one end of a piece of chain, the other being connected to the cutter bar. With this arrangement the cutter bar is most readily adjusted to any required height suitable for the crop to be cut, by a simple upward or downward movement of the hand lever, and requires no further attention until the re-adjustment of the cutter bar is necessary.

Fig. 1, in the accompanying engraving, is a side elevation of the main portion of a reaping or mowing machine, arranged according to these improvements; and fig. 2 is a corresponding plan of the same,

The frame A of the machine is formed of cast iron, and consists of a single piece, formed of a suitable shape, to receive the shafts and other working gear or parts requiring to be attached thereto. On the upper part of this frame depressions are made to receive the bearings of the main driving shaft B; or in lieu of the bearings being fitted with covers as shown in the drawings, two tubular bosses may be formed in the frame for the shaft to work in. On the outer end of the shaft B is keyed the wheel C, which forms the principal bearing and driving wheel of the machine, the motion of which drives the other moving parts of the apparatus. The other side of the machine is supported by the smaller bearing wheel D, the adjustable supporting stud of which is carried in the bracket E that is bolted to the finger bar F; the other end of the finger

bar is bent upwards and attached by the bolts to the bracket G, and secured to the side of the frame A, and further secured by the strong angular stay F^1, the front part of the bar being furnished in the usual way with the fingers H for dividing the standing crop. To each side of the frame A is hinged and secured a strong knee-piece or bent arm I, and to these knee-pieces is attached the front frame J, the side pieces of which form the horse shafts. An eye is formed at K in a backwardly projecting part of the frame A, which is intended to receive the lower end of a bent rod carrying the seat for the driver. On the shaft B is a coupling L, by means of which the motion of the shaft is communicated at will to the bevel wheel M, fitted loosely on the shaft B, the hand lever for operating the coupling L, being of the usual construction, is not shown in the drawings. This wheel gives motion to a pinion N carried on the shaft O, which is arranged in a slightly angular position, the bearings being carried in parts formed for the purpose in the frame A. On the front end of the shaft O is a spur wheel P, which drives a pinion P^1, keyed on the outer end of the crank shaft Q. The crank of this shaft is connected by the rod R to the cutter bar S, which thus receives its reciprocatory movement from the crank. The brackets E and E^1 are attached to the finger bar F, the extremities are enlarged laterally, and have holes made in them to receive and admit of the adjustment of the end journals T, which partially support and regulate the angle of the platform U, on to which the cut crop falls. At the outer side of the machine, contiguous to the wheel D, is a guard V, which serves to divide the standing corn and direct it inwards towards the fingers H of the bar F. This machine is also provided with an improved arrangement for regulating the height or distance of the finger bar from the ground, so that it may be adjusted to suit the crop to be cut as well as to keep it clear of any inequalities of the soil. To the sides of the malleable iron knee-pieces I, are bolted the bracket bearings W and W^1; the bracket W is cast in one with a double segmental piece, so as to admit of the lower part of the hand lever X passing between the faces of the segments. The lever X is keyed to the transverse shaft Y, which is carried in the brackets W and W_1, and the lever has formed on it a small laterally projecting pawl or tooth, which takes into the ratchet teeth that are formed on the contiguous face of the segment. The lever is kept in gear with the ratchet teeth, when not otherwise acted upon, by means of the blade spring Z, which presses against the opposite face of the segment. On the other end of the shaft Y is fitted a segmental pulley a, to which is attached one end of the chain b, whilst the other end is fastened to the front part of the frame A. When the driver is seated on the machine, the lever X is within convenient proximity to his right hand; and when he desires to raise the finger bar F, he simply draws the lever X backwards towards him; but when he has to lower it, the lever has to be drawn to one side, so as to release it from the ratchet teeth, then move it in a forward direction to the extent that he requires the finger bar to be lowered. When the lever is released, the spring Z presses the pawl on the lever into the ratchet, and the lever is retained in that position. The partially rotary motion of the shaft Y raises or lowers the chain b, and with it the front part of the machine, bringing the finger bar to the required height, and thus adjust, the cutters to suit the crop to be operated upon.

The arrangement of the adjustable lever is applicable to other kinds of reaping or mowing machines, as well as the particular modification hereinbefore described and shown in the accompanying drawings—as, for example, in applying this arrangement to the kind of reaping or mowing machine known as the "Buckeye reaper," the shaft Y is arranged across the carriage of the machine, and the free end of the chain b is attached directly to the finger bar. With these improvements, reaping or mowing machines are rendered stronger and more compact, whilst the adjustment as regards the height of the finger bar is more readily effected.

LAKE SUPERIOR COPPER WORKINGS.

A LARGE and most interesting pamphlet, by Charles Whittlesey, Esq., "On Ancient Mining on the Shores of Lake Superior," has been published, in New York, as one of the Smithsonian contributions to knowledge. The author has devoted much attention to this subject; and maps of the country, with engravings of old mines and the relics found in them, are contained in this publication. We here learn that evidences of ancient mining operations were first brought to public notice in the winter of 1847-8. The Jesuit Fathers who first visited that region announced the presence of native copper in large masses; and boulders of copper had been found many years ago scattered among the drift gravel, from Lake Superior to Rocky River in Ohio; but no ancient workings were known till the period mentioned above. In casting the eye over a map of Lake Superior, a remarkable projection in the form of an immense horn, is observed jutting out from the south shore and curving eastward. This is Keweenaw Point, which is about 80 miles in length and 40 in width. Through the whole of this extent of projection, a belt of metalliferous formation extends; and within this all the copper mining operations—ancient and modern—have been contined. The most remarkable feature of this metalliferous region is the character of its products, which occur, not as an ore of copper, but in masses, veins, and rounded nodules of the metal itself.

The first actual mining operations here were commenced in 1761 by Alexander Henry, but they proved abortive. In 1841, Dr. Douglas Houghton made a report to the Legislature of Michigan, conveying very definite information respecting the existence of native copper in Lake Superior; and shortly after this, fresh mining operations were commenced, and speculators flocked in from all quarters. In 1848, Mr. S. O. Knapp, agent of the Minnesota mine, made the first public announcement respecting the discovery of ancient mines and the relics of an ancient mining population. This created a sensation far and near, and subsequent explorations have led to the discovery of very many ancient pits. Most of the ancient diggings have been found in dense forests, and outwardly consist of irregular shallow hollows, which had been previously noticed without thought of their real character. There are three groups of ancient mines corresponding with the modern mines in this region. In these old pits, hard stone malls and hammers have been discovered; also copper hammers, spear heads, gads, arrow heads, and knives; and wooden shovels, levers, and a ladder. During the past summer, several of these old mines were discovered in the Ontanagon district, and from one a bag of untanned leather in a perfect state of preservation was taken, and has been considered one of the greatest of ancient curiosities. Who these olden miners were, is a puzzle to antiquarians. But providentially they have done great service to us, for our practical modern copper miners regard the old pits as pretty sure guides to valuable copper lodes. When an old pit is found, it is cleared out and explored, and generally the miners are rewarded by finding rich masses in the excavation. These ancient miners seem to have possessed quite as accurate a knowledge of the copper veins as the most skilful and intelligent modern mineralogists and miners. In a certain sense they were our mining pioneers. They do not seem to have been acquainted with the art of smelting copper, and were unacquainted with the use of iron; therefore their efforts at mining were rude; still they have left evidences of being an ingenious and skilful people. Mr. Whittlesey entertains the opinion that these ancient miners were not of the present Indian race. As yet no remains of cities, no graves, no domiciles or ancient highways have been found in the copper region. These old miners appear to have been further advanced in civilization than those whom we call aborigines. Trees standing upon the old pits are about 300 years old, and beneath these lie the rotten trunks of a still earlier period. When the ancient miners lived is unknown; but these mines must have been abandoned at least from 500 to 600 years preceding the present age. Who they were, where they came from, and whither they went, in all likelihood, will never be known.

The copper mining business in the Lake Superior region is in a very prosperous condition at present; and we learn, from the *Mining Gazette*, that a new copper-smelting establishment is now in operation on Portage Lake; which, with the one recently erected in California, will make eight now in operation in the United States.

VENTILATION OF MINING TUNNELS.

A MOST important feature of the expense of mining tunnels of any great length in America has heretofore been absorbed in the supposed necessity for sinking air-shafts every few hundred feet. We have frequently alluded to the bad management, or rather, lack of knowledge of the principles of ventilation in underground operations, both in driving tunnels and in drifting perpendicular openings, or shafts. A late number of the Virginia City *Union* gives the following very good plan recently adopted at the famous Latrobe tunnel, in Virginia City:—

When this tunnel had reached a length of only a few hundred feet it was found necessary to sink an air-shaft, and at F-street another; at this point the bottom of the shaft was closed up, with the exception of a hole about 10 in. square, through which passed a wooden box flue of that size, by which the air is conducted into the further extremity of the tunnel. The draught is so strong, that, notwithstanding the tunnel is west of A-street, no other shaft has yet become necessary, and it is thought that no more will be required, as it will be but a short time before it connects with the works on the Comstock. A candle held at the mouth of the flue will be instantly extinguished. Throughout the whole of the great distance which this flue supplies with air, the tunnel is cool and pleasan, and a person can breathe with almost as much easte as in the open air. This plan of ventilation was first suggested to the superintendent of the tunnel, we understand, in reading the translation of an old German work on mining.

The Latrobe tunnel is now in about 2,600 ft., and is in daily expectation of reaching the ledge (Comstock), which it will strike at a depth of 465 ft. from the surface.

The Santa Fé mine, also in the Virginia City district, is ventilated on a similar principle. A tin tube, some 4 in. in diameter, is connected with a tall wooden flue, standing in and reaching to the surface of an air-shaft, and running back from the bottom of the shaft to the furthest end of the tunnel, where the drifters are employed.—*California Mining Journal.*

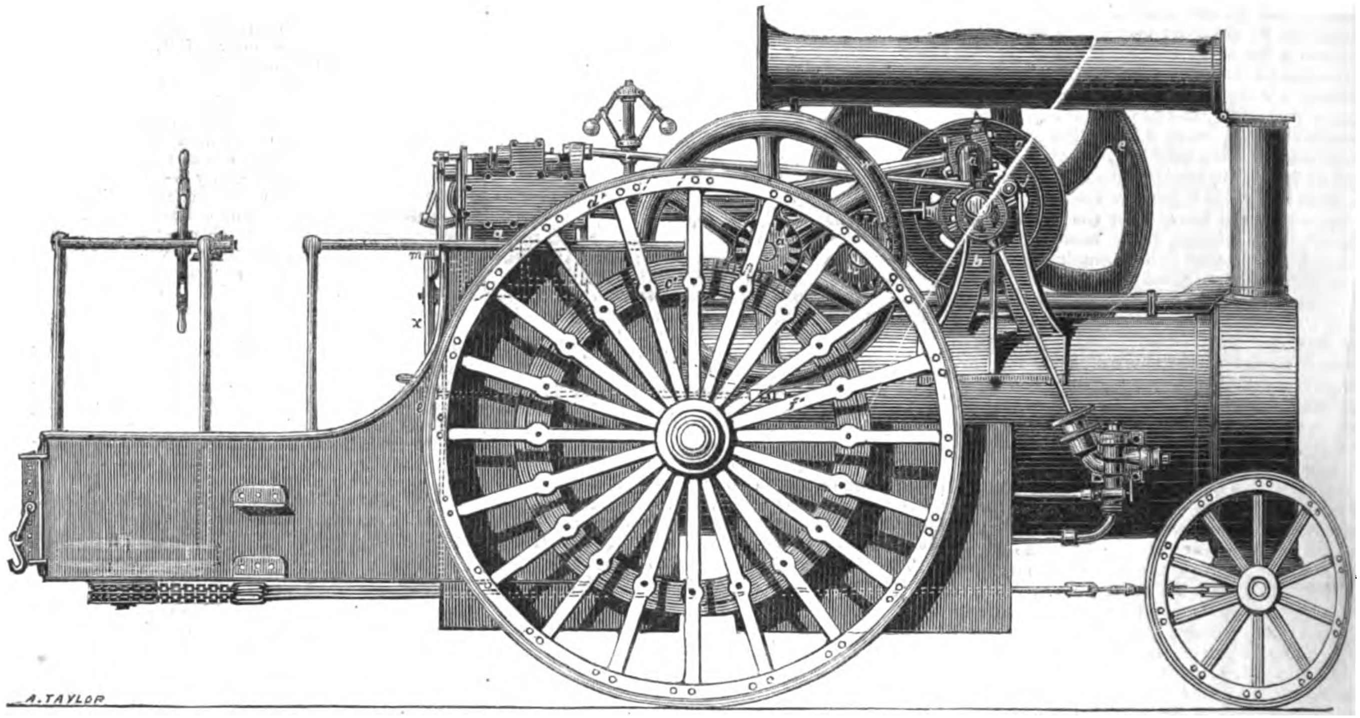
PHOTOGRAPHY BY THE AID OF ARTIFICIAL LIGHT.

A FRENCH *savant*, M. M. A. Gaudin, has invented a new lamp, by the aid of which the photographer can employ the hours after sunset in multiplying negative copies from the positive pictures obtained during the day. A light of the kind required has long been sought for, even before the art of photography was understood, for the purpose of lighting ships and signalling.

Oxygen, expelled from a receiver by any convenient degree of pressure, passes into a receptacle containing ether, or some spirit rich in hydrogen; on issuing from this it will, if ignited, burn precisely like alcohol. If, however, we cause the saturated gas to mingle with a stream of pure oxygen, flowing from the first-mentioned receiver, the force of the currents being regulated by suitable stopcocks, the jet of flame impinging on a cylinder of lime produces an intense light, resembling Drummond's in every particular. M. Gaudin's experiments are very interesting, as they apparently supply us with a means of obtaining the Drummond light with oxygen alone, thus obviating to a great extent the risk which has hitherto attended the use of that light. We much fear, however, that the high price of oxygen gas must, except in exceptional circumstances, preclude anything like a general adoption of the invention.

The trial of a newly-invented lamp for lighting railway platforms, goods' stations, &c., took place on Friday evening last, at the Devonshire-street depôt of the Great Eastern Railway. There were present Captain Belfield and Captain Martindale, who attended by order of the Secretary of State for War, and representatives of all the principal railways which run into London. The yard of the depôt in question is about a quarter of a mile in length, and, although four of the new lamps are erected, only two were used. The light from them was found amply sufficient to enable the workmen in every part of the yard to dispense with the ordinary hand-lamp hitherto in use. Indeed, such was the illuminating power of the light that small print could be read with facility at a distance of 45 yards, and the scientific men who witnessed the effect expressed their entire satisfaction with the result of the trial. The lamps are constructed and fixed upon the principle invented by Dr. Brown, late of the Royal Navy, and are already in general use on the Great Eastern Railway.

BIDDELL'S TRACTION ENGINE.



BIDDELL'S IMPROVEMENTS IN TRACTION ENGINES.

THESE improvements, patented by Mr. George Biddell, mechanical engineer, Ipswich, consist in the application and use of a friction clutch or clutches in combination with suitable driving and disengaging gear. The piston rod of the steam cylinder gives motion to the main or crank shaft, on which the friction clutches are by preference placed, although they may be placed on an intermediate shaft, one part having a sliding motion thereon, but always turning with it, whilst the other part which carries a toothed wheel is capable of turning thereon freely when the two friction clutches are not pressed together. On the main or crank shaft is a fly-wheel. The toothed wheel carried by the friction clutches gives motion to another toothed wheel fixed on a second shaft, on which second shaft are two toothed pinions which turn with but can slide on that shaft; these pinions are coupled together by a double crank, connecting rods, and forked levers, or other suitable contrivance, in such manner that when one is moved out of gear with its wheel the other is moved into gear with its wheel. The crank by which these two pinions are slid, is on a separate shaft having a lever handle thereon, by which it can be turned in one or other direction at pleasure, and by the interposed mechanism slide the two pinions. One of these toothed pinions works in the teeth of an internal wheel, whilst the other works in the teeth at the periphery of a wheel of lesser diameter, but both these wheels are fixed on the same shaft. There are also two toothed pinions on this axle or shaft, which rotate with, but are capable of sliding on, the ends of this shaft or axle, so that either or both of such pinions may be in or out of gear with spur wheels carried by the two main road wheels.

These improvements give increased facilities in working; they do away with the usual reversing slide gear, and admit of a single cylinder engine being as efficiently used as one with a double cylinder, thus giving greater simplicity and economy, as also less wear and tear.

The accompanying engraving, represents a side elevation of a steam traction engine, combined or arranged in accordance with these improvements. *a* is the steam cylinder of the engine, firmly attached to the boiler and connected with the crank shaft brackets *b*, *b*, by the two stay bolts *c*, *c*. Motion is communicated to the crank shaft *d* from the piston by its rod and connecting rod in an ordinary manner, there being guide bars, cross-head, slide valve, eccentric, and parts in connection therewith, also a governor, throttle valve, starting valve, and feed pump—all which are arranged as heretofore. The starting gear, worked by a man at the back of the engine, is of the usual kind, and needs no description. *e* is the fly-wheel on the engine shaft; *f* is a small pulley fixed at the end of the crank or engine shaft, both of which can be used for driving suitable machinery when required, as by an ordinary portable engine; *g* is the external part of the cast-iron friction-clutch, having a cog wheel *h* securely bolted to it. Upon the largest diameter of this part of the clutch a wrought-iron hoop is shrunk to give additional strength. This portion of the clutch, with its cog wheel *h*, is free to turn upon the engine shaft, except when the other portion of the clutch is pressed into it, when it must revolve with that shaft. The whole clutch is kept in its position endways on the shaft by fixed collars. The internal part of the clutch is provided with its six sets of radial knuckle joints and screws and adjusting nuts. This portion of the friction-clutch is always obliged to rotate with the crank shaft of the engine, being carried round by a key, but is capable of sliding endways. The hand wheel *m* gives motion to a screw through the small pair of bevel wheels, which screw acts directly upon a forked lever, which receives two projections of a collar (made in halves) spanning a recess in the boss of the part *i* of the friction clutch. By these means the friction surfaces of the clutch can be brought into powerful contact or released with perfect command, thus communicating motion to the gearing at pleasure, whilst the engine is running, and without the necessity of stopping the engine shaft and piston. *r* is a cog wheel fixed to its shaft *s*, gearing into the wheel *h*. The shaft *s* carries two pinions *t* and *u*, which always turn (by means of proper keys) with the shaft *s*, but are capable of sliding upon it, so as to be put in and out of gear with their respective wheels *v* and *w*, by means of the handle and rod *x*, and a proper arrangement of levers, cranks, and rods, which arrangement is to be such that the two pinions *t* and *u* shall not possibly be both in gear or in action on their respective wheels at the same time. By one action of the handle *x* and double crank *y*, one pinion is always fairly withdrawn from acting on its wheel before the other pinion enters into gear or acts on its wheel. The wheel *v* and internal wheel *w* are both firmly fixed to the shaft *z*, upon which also there are two pinions, which are made to turn with this shaft, but are capable of being moved endways upon it by means of forked levers, so that they can at pleasure be easily engaged or disengaged with their respective wheels, which are firmly attached to the main road or driving wheels. Upon the exterior circumference of the internal wheel *w* a single clip break is arranged, which is operated upon by means of a hand wheel, and a right and left hand screw.

It will be readily seen that, by means of the friction-clutch and the arrangement of the gearing and the disengaging levers and rods as described, whilst the engines, piston, and crank shaft are running, the forward or backward motion of the entire machine can be started, stopped, or reversed at pleasure without stopping or reversing the motion of the engine shaft and its fly-wheel, thus giving increased facilities and obvious advantages in using the power of the engine.

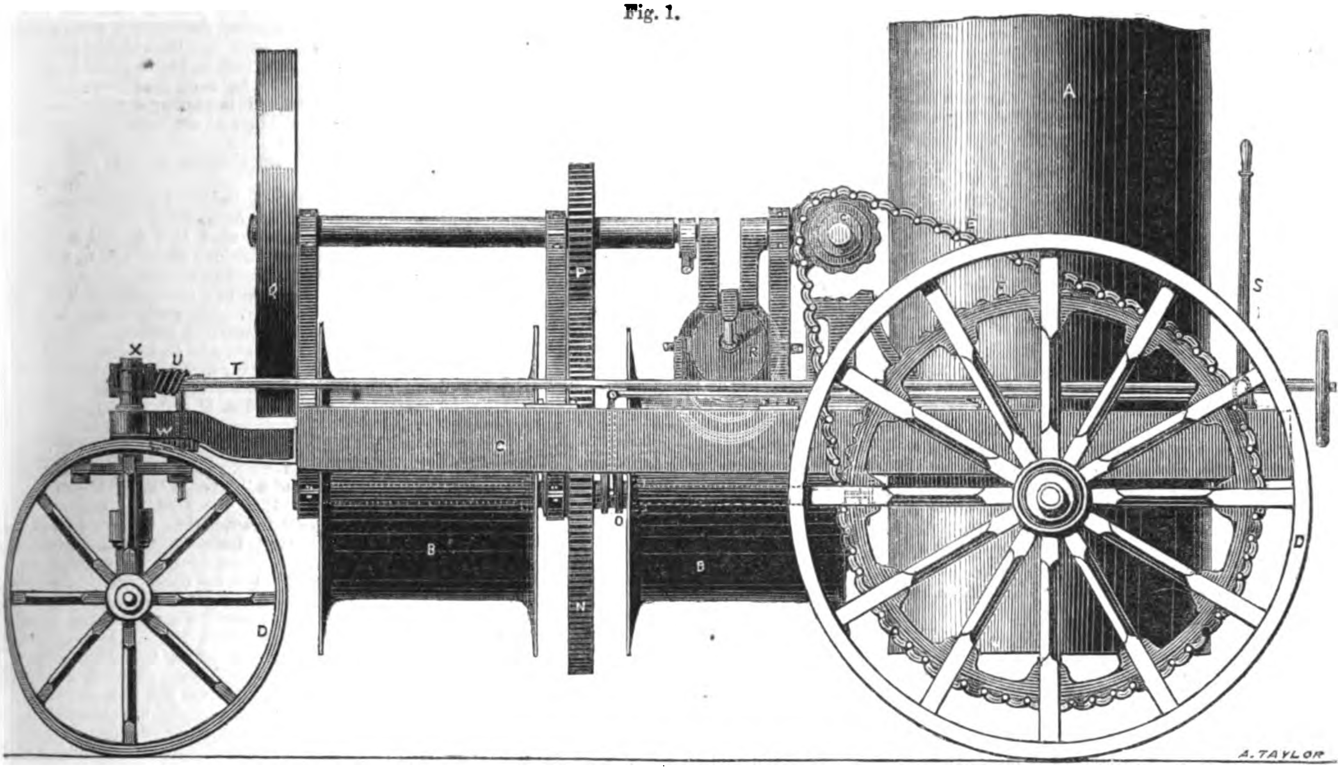
F. AND A. ROBERTS' IMPROVEMENTS IN AGRICULTURAL IMPLEMENTS.

THIS invention, patented by Messrs. F. and A. Roberts, of Gloucester, comprises various improvements in agricultural implements, and in apparatus for working the same, being more particularly designed for application in the cultivating system, wherein two reversed sets of ploughs or other agricultural implements are drawn backwards and forwards between a steam engine and a stationary pulley or anchor, or two steam engines, or two anchors, some of the improvements being also applicable otherwise.

In one modification of the portion of the improved arrangements in immediate connection with the ploughs or implements there is centrally a kind of carriage or framing resting upon three wheels, which are adjustable as to height, one of which (a large one) runs in the furrow on one side, whilst the other two (being small ones) run on the land or top surface on the other side. A barrel is mounted loose on a transverse horizontal shaft forming part of the carriage framing, and at opposite ends of this barrel there are discs or

F. AND A. ROBERTS' AGRICULTURAL IMPLEMENTS.

Fig. 1.



levers, to the opposite points of which are jointed the inner ends of two frames, having the ploughs or other implements attached to them. These frames lie in opposite directions, and when the barrel is turned to place one frame in its lowest position the other frame will be in its highest position. The outer ends of the plough or implement frames are formed with sockets, through which pass vertical spindles fitted with swinging or castor wheels at their lower ends, and the outer frame ends are moved up or down these spindles simultaneously with the upward or downward movements of the inner frame ends by means of ropes led from the barrel to pulleys at the heads of the spindles; or other equivalent mechanical means, may be adopted to keep the plough or implement frames parallel, or nearly so, whilst being moved up or down. The draught of the hauling rope is made to draw down the proper plough or implement frame into its working position at each traverse, and for this purpose there is upon the barrel a double-grooved pulley or sheave, which can be put into or out of gear with the barrel by an ordinary clutch and lever. The rope ends are attached one to each part of the pulley, both ends being led upon it underneath. With this arrangement it follows that when one rope (that to the right, for example) is hauled tight, the barrel is turned down on the left-hand side, putting what is then the after set of ploughs or implements down into their acting position, the strain being applied in a very effective way for forcing the ploughs or implements down into the soil. To facilitate the shifting of the apparatus at the headlands, and otherwise, the central carrying wheels are made to swivel for steering purposes. In a simple arrangement for steering these wheels a bevelled tooth sector is fixed on the vertical spindle of the large wheel, this sector being connected by cross links to levers on the vertical spindles of the two wheels on the opposite side. The toothed sector is acted upon by a bevel pinion on a spindle fitted with a hand wheel. Other implements instead of ploughs may be attached to the frame.

In one modification of the portion of the improved arrangements relating to the haulage of the implements, a steam boiler (vertical by preference) is employed to admit of the hauling or winding drums being conveniently mounted independently of it, but on the same framing. The framing is (by preference) rectangular, and the boiler is placed at one end between the main driving wheels. At the other end there is (by preference) a pair of smaller wheels arranged with swivelling gear for steering purposes. These wheels may also be arranged to rock, so as to accommodate themselves to inequalities in the ground surface. The winding drums are mounted on a horizontal shaft disposed longitudinally, and the first motion shaft is placed in a parallel position above. The first motion or crank shaft is actuated (by preference) by two steam cylinders placed above one of the drums, and the drums are actuated by a pinion on the first motion shaft in gear with a spur wheel on the drum shaft, a clutch or clutches being provided for throwing either drum into or out of gear. For actuating the driving wheels, toothed rings or wheels are fixed or formed on the inner faces thereof, and these toothed rings are encircled by endless chains driven by toothed pinions on a transverse horizontal shaft, receiving motion from the first motion shaft by means of three bevel wheels with clutch for giving motion in either direction. On the end of the first motion shaft there is a fly-wheel shaped to act as a driving pulley when it is wished to employ the engine for actuating thrashing or other machines. The framing may be continued beyond the boiler to support a water tank and coal box and a platform for the driver; the framing also may be made hollow, so as itself to form a tank, if preferred, and the various levers for controlling the working of the engine may be arranged conveniently to the driver's hand. The anchor, with guide pulley for the headland opposite to that at which the engine is placed, consists simply of a kind of triangular or other form of frame mounted on three or four wheels, one or two whereof being arranged to swivel for steering. The guide sheave or pulley is on the lower end of a vertical spindle hung in bearings on the frame, and on the upper end of this spindle there is a bevel wheel in gear with another bevel wheel on a short horizontal spindle, with clutch for putting them into or out of gear. The horizontal spindle has a pinion on one end, which gears with a toothed ring or wheel fixed or formed on the inner face of one of the carrying wheels, and by this means the anchor is rendered self-moving. The axle of the main carrying wheels may be shifted upon the frame in order to lift the guide pulley or sheave higher off the ground when travelling. Flange pieces are provided to bolt to the wheels for the purpose of penetrating the soil, and so resisting the lateral strain on the anchor. The parts of the apparatus may be combined in various ways besides that described; thus one plough frame or different implements may be attached directly to the engine which may itself be made to traverse backwards and forwards over the ground, and in this case the winding drums may be removed from the engine if wished.

Fig. 2, the accompanying engraving, is a cross

Fig. 2.

section or end view of a set of ploughs with one frame removed.

The parts marked with the letter A are the frames which carry the ploughs or other tilling tools or implements, or to which they are attached; B are the wheels on which the apparatus travels; C are the discs on the ends of t

barrel to which the frames are attached, and by which the implements are raised from and lowered to their work; ropes or chains pass over or around one of the discs, and under pulleys in the ends of the frames, and are attached to loops on the top ends of the vertical spindles of the castors or end wheels; F is the barrel, which runs loose on a transverse spindle or shaft G, to which also are attached the bearings K for the axles L of the carrying wheels; H is a circular piece with two grooves, to which the draft ropes are attached, which also forms a clutch or catch box capable of being moved on the barrel by means of a lever I, hinged in cross bars g attached to the axle bearings. This clutch runs loose on the barrel, except when moved into contact with a corresponding clutch F^2 formed on the barrel. The wheel axles L are vertical at the fixing part, and pass through bearings K attached to the ends of the shaft G. These axles are capable of swivelling for the steerage of the apparatus by means of a bevelled toothed sector M fixed on the top of one axle gearing with a pinion fixed on a shaft N, on which is a hand wheel O. Levers are also fixed to the axles, and connected with each other by rods, so that in turning one axle by the hand wheel all the axles will thereby be turned, and the wheels thus swivelled. The height of the carriage from the ground, or the depth to which the ploughs or implements are required to penetrate the ground, is regulated or adjusted by means of nuts screwed on the vertical parts of the axles.

Fig 1 is a side elevation of the combined engine and windlass. A is the boiler, and B, B, the winding drums carried by the same frame or carriage C. The frame C may be constructed so as to form a water tank for the supply of the boiler. D, D, are the travelling wheels, the front or smaller ones being made to rock and swivel, a method of steering them being hereinafter shown. E are the toothed rings or chain wheels fixed on the travelling wheels, encircled by chains F passing over the pinions G, carried by the cross shaft H. This cross shaft also has two bevel pinions I, which turn loosely on it, and gear with another bevel pinion J, keyed on the crank shaft K. On the shaft H, and between the pinions I, is a clutch L, which is made to slide on the shaft. The clutch has projections at both of its ends, and in the pinions I are corresponding recesses. When, therefore, the clutch is thrown out to the right hand, the right-hand pinion will become fixed on the cross shaft H, and in revolving will of course carry the shaft with it, giving motion to the travelling wheels in one direction, and when the clutch is thrown to the left the same effect follows, only the direction given to the travelling wheels will be opposite to the former. When stationary, the clutch is midway between the pinions I, and the shaft H is at rest. By this arrangement the usual link motion is disponsed with, the engine never requiring to be reversed. M is a lever for throwing the clutch L into or out of gear with one or other of the wheels I. Each of the drums has a suitable rope, to which the plough or cultivator is attached—one of them winding up its rope as the implement approaches, and the other unwinding; and as the implement returns to the anchor, *vice versa*. The drums are not keyed to the horizontal spindle, but turn loosely on it; while at work, ploughing or cultivating, it is necessary at each traverse of the implement, to throw one drum out of gear and the other in. This is done as follows:—The large gear wheel N runs loosely on the horizontal spindle that carries the drums, and a projecting boss thereon, forming a neck, is supported by a bearing on the frame of the carriage, betwixt which and one of the drums is a clutch O, which slides on the spindle and has projections which pass through the boss of the said wheel, and enter the drum when moved in that direction, also having other projections which enter the other drum when moved in the opposite directio[illegible]equently each drum will be thr[illegible] out of gear as the clutch is thr[illegible] left. In this way, on the ploug[illegible]adland, there is no necessity for stopping or reversing the engines. The gear wheel N is actuated by the pinion P keyed to the crank shaft K, on which shaft is the fly-wheel Q, which may be available where not employed in ploughing for giving off the power of the engine for thrashing, grinding, pumping, or any other sort of work required. The shaft K is driven by two oscillating engines fixed on the framing, one of which is shown at R connected to one of the cranks. S is the lever for working the clutch O, and T is a spindle on which is a worm U gearing with a wheel V on a short shaft, on which is a wheel in gear with a sector W on one of the axles of the front wheels, which is connected by rods and levers to the other, whereby they are swivelled, and the engine steered as required. The said front wheels are also capable of rocking or rising and falling, according to the undulations of the ground, by having the axle frames hinged in the middle at X. The framing may be brought back behind the boiler, and made to support a small tender for coal, water, and a platform for the engineman. The engine, windlass, and steering are all managed at the boiler end, as shown. The framing itself may form a tank.

A NEW WANT IN AMERICA.

The following highly suggestive paragraph appeared in the *American Railway Times* a week or two back:—The breaking-up of the system of slave labour in the Cotton States consequent upon the rebellion, opens a new field of experiment for our inventors and mechanics. The cotton, rice, and sugar fields are to be cultivated by free labour, and, as a necessary consequence, by labour-saving tools and machinery. Instead of the scratchy hoe and the mule plough for breaking up the cotton lands, there must and will be steam ploughs introduced and used. The cotton lands are particularly adapted for the use of the steam plough; being mostly quite level, and the soil strong and compact. These lands having been worked for years mostly on the surface only, steam ploughs that will go 16 in. or 18 in. deep, will bring to the surface the elements of fertility so long neglected and unused; and plantations that are now comparatively valueless under the very superficial cultivation of slave labour, can be made mines of wealth to the country. What is now wanted is *the* steam plough that is best calculated for this service. The population for tending and picking the cotton are all on the lands ready for the service, and under efficient steam ploughing and intelligent free-labour culture, the crops may easily be doubled. Who has got the best steam plough?

TO CORRESPONDENTS.

The Mechanics' Magazine is sent post-free to subscribers of £1 1s. 8d. yearly, or 10s. 10d. half-yearly, payable in advance. Post-office orders made payable to Mr R. A. Brooman, of 166, Fleet-street, E.C.

Advertisements are inserted in the Mechanics' Magazine at the rate of 6d. per line, or 5½d. per line for 6 insertions, 5d. per line for 13 insertions, 4½d. for 26 insertions, and 4d. a line for 52 insertions. Each line consists of about 10 words. Woodcuts are charged at the same rate as type. Special arrangements made for large advertisements.

All communications should be addressed to the Editor, 166, Fleet-street.

To insure insertion in the following number, advertisements should reach the office not later than 5 o'clock on Thursday evening.

Received.—Messrs. S. and Co., J. W., J. H., S. D., J. N., M. L., W. B.

A. Y. (Belfast).—We must refer you to our advertising columns.

D. K. (Wolverhampton).—Certainly electricity and magnetism mutually produces each other.

Shafting (Truro).—You only give the length of your shaft and its diameter; you do not state what the length of your crank is, and therefore it is impossible that we can say what amount of torison is produced by the pressure on your piston.

T. K.—A boiler 4 ft. in diameter, and 5-16th thick, if of fair iron, will stand 60 lbs. strain with ease. We do not approve of angle iron bridge stays across the back plate of a fire-box shell; they usually throw a peculiar and injurious strain on the corners of the plate.

Correspondence.

NEW SYTSEM OF ARMOUR PLATING.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

Sir,—I noticed in your valuable paper of the 13th inst., a description of the American-clad warship, "Dictator," from the designs of Captain Ericsson, and was struck with the similitude that this improved "Monitor" appears to have, with regard to its armour and turret, with Mr. John Walker's floating battery, described in your number of the 25th of July, 1862, and for which he took out, about that time, a patent in England and France.

It may therefore be said, that these improvements were known in this country seventeen months ago; and the first ideas do not come from America, but from England.

Your obedient servant,

A. Ragon.

14, Caroline-street, Bedford-square, London,
November 30th, 1863.

P.S.—I have presented this invention to the French Naval and Military Departments, where it has been most favourably received.

[We willingly give our correspondent's letter a place in our columns. We early traced the similarity between the American system, as applied to to the "Puritan," &c., and that invented by Mr. Walker, who is really entitled to all the credit which can accrue from what seems to us to be a very valuable invention.—Ed. M.M.]

NARROW GAUGE LOCOMOTIVES.

Sir,—Until I read the account in your Magazine of the 27th ult., of a "Narrow Gauge Locomotive," I was not aware that the slightest difficulty had been experienced in supplying the want for these which you indicate. Unless I am much mistaken, there are at least a dozen firms in the country, who might have undertaken the construction of engines for the Port Madoc line without hesitation; and those who are acquainted with what has been already accomplished in the North for colliery and mineral lines, will be surprised to be told that anything novel or extraordinary has been achieved in the case which you mention. I could not have credited that—as stated—the late Mr. Robert Stephenson pronounced upon the impossibility of constructing such an engine as was required, and am tolerably confident that the firm of Stephenson and Co., would for the last dozen years have seen nothing impossible about the scheme; though it might not suit them to undertake the construction of a few such engines. The ingenious juxtaposition of the name of the prejudiced and obstructive Stephenson with that of the clever young gentleman just out of his apprenticeship, would be creditable to the skill of an unscrupulous puffer, but can only excite the ridicule of those acquainted with the past history and present position of Locomotive Engineering.

Your obedient servant,

A.

Meetings for the Week.

Mon.—*Soc. of Engineers*, "Steam Navigation on the Indus," by E. Warren, Esq., at 7.15 p.m.
Royal Inst., General Monthly Meeting, at 2 p.m.
Medical Soc., Lettsomian Lecture, at 8.30 p.m.
London Inst., "On English Costumes from the Anglo-Saxon Period," by Rev. Henry Christmas, F.R.S., at 7 p.m.

Tues.—*Inst. Civil Engineers*, 1, Continued Discussion upon Mr. Morshead's Paper "On Cornish Pumping Engines." 2, "On the Closing of Reclamation Banks," by J. M. Keppell, Esq., at 8 p.m.

Thur.—*Royal Soc.*, at 8.30 p.m.
Antiquaries, at 8 p.m.
London Inst., "On the Principles and Applications of Organic Chemistry," by J. A. Wanklyn, Esq., at 7 p.m.
Inventors' Inst., "On Inventions for Improving Pavements with the view of rendering them clean, durable, and safe," by Robert Saunders, Esq.

Fri.—*Architectural Assoc.*, Prize Essay or Vaulting and Groining, at 8 p.m.

Miscellanea.

Samuel Hall, Esq., C.E., whose name is familiar to almost all connected with engineering science (brother to the celebrated physician and physiologist, Dr. Marshall Hall), died in London a few days ago at the age of eighty-three years. In a list of twenty-one inventions patented by Mr. Hall, we find those for the gassing, starching, bleaching of lace and other fabrics by which his native town of Nottingham and the surrounding country have derived so much wealth and fame. He also devoted a considerable amount of time and money to the improvement of the steam engine, the prevention of smoke and boiler explosions, and was the patentee of the "Surface Condenser" which is now occupying such a large share of attention in connection with marine engineering, and which invention was applied with considerable success by Mr. Hall to the "Sirius," the first steamship that crossed the Atlantic with steam alone.

The "Golden City," a fine American steamer, recently built, has made a remarkable voyage to California. The "Golden City" has an overhead beam, single cylinder engine, of 105 in. diameter of cylinder and 12 ft. stroke of piston, built at the Novelty Iron Works, New York. This new steamer arrived at Panama direct from Rio (not touching, as usual, to coal at Lota), October 24, in 41 days 15 hours running time from Canal-street wharf, New York; whole distance 11,166 miles. The greater part of the Atlantic voyage she experienced head winds with heavy seas. From the Straits to Panama she averaged 305 miles a day, and for the whole voyage 268 miles a day.

We learn that an arrangement has been entered into between the Government and the Montreal Steamship Company, in pursuance of which the latter will receive another contract for the performance of the ocean mail service. The precise rate of payment has not been stated; but it is known to be much smaller than the sum paid under he contract which Ministers abrogated. Care will also be taken so to prepare the agreement that the public shall have stronger guarantees of safety, and of an efficient performance of the mail service, than were formerly provided.

Some time ago a splendid stick of white oak timber was landed at the Globe Works, Boston. It was one of the largest ever brought into Boston. It measured 66 ft. in length, and was hewn up square, on the average, 28 in. by 29 in. It contained 370 cubic feet., equal to 4,440 ft. broad measure, or 9½ tons. Its actual weight would not be less than 12 tons. It was brought from the State of New York.

Captain Alexander Bowers, of the Royal Navy Reserve, has performed an exploit as important, if not as interesting, as the discovery of the source of the Nile. He has taken a 1,000-ton ship into the heart of China, ascending the Yang-tse to Hankow, the great tea *entrepot*, 1,400 miles, by map measure, from Shanghae. He found a great city and flourishing trade, with about thirty British hongs, built upon land granted by the Chinese Government, more hongs building, and every sign of great commercial prosperity. A club-house and church are building, and, of course, the third sign of civilization—a gallows—cannot be long delayed. The anchorage opposite the town is fairly safe, the risk of voyage is not excessive, and there seems little doubt that Hankow will henceforward be in direct communication with London. This is really a great result from the capture of Pekin, the valley of the Yang-tse being as productive as that of the Ganges.

A Frenchman has discovered a substitute for paint over plaster. A coat of oxide of zinc, mixed with size, and made up like a wash, is first laid on the wall, ceiling, or wainscot, and over that a coating of zinc, prepared in the same way as the first wash is applied. The oxide and chloride immediately effect a sort of combination, forming a cement, smooth, and polished as glass, and possessing the advantage of oil paint without its disagreeable odour.

The Lords of the Admiralty have entered into a contract with Messrs. J. Brown and Co., of Sheffield for the supply by that firm of upwards of 1,000 tons, of armour-plating for the iron-cased frigate "Lord Warden," at Chatham. The armour plates with which the "Lord Warden" will be covered will be 5½ in. in thickness for her lower broadside tiers, and the remainder 4½ in. in thickness; the "Lord Warden" differing in this respect fron the other armour-plated frigates in having her armour-plates of the same thickness on the stem and stern as on her broadside. The blocks for the new frigate have been laid on number No. 7 slip for some time, and the frame cut out; but in consequence of all the available hands at Chatham having been employed for several months past in completing the "Achilles," the commencement of the "Lord Warden" has been unavoidably delayed.

The armour-plates tested at Portsmouth on the 13th inst., a report of which appeared in the *Times* of the following day, have been taken off the sides of the "Monarch" target-ship and landed at Portsmouth dockyard, in order that their reverse sides might be examined by the members of the Iron-plate Committee and further reported upon. Two of these plates, sent in by Messrs. Cammell and Co., of the Cyclops Works, Sheffield, have attracted much attention by their excellence of material and manufacture, coupled with the fact of their being the first essay of their makers in the production of armour-plates, and, it is stated, the only instance in which any firm have succeeded in passing the Admiralty standard with so high a figure of merit on a first trial. One of these plates was of 5½ in., and the other of 4½ in. thickness. An examination of the reverse side of both discloses very little damage; and what openings there are in the metal run in the direction of the fibre, both plates being remarkable for the absence of vertical cracks or openings, and of any connection between what openings exist and the boltholes. The welding of both plates was found to be perfect. The 5½ in. plate on the day of trial received shot in a space measuring 34 in. by 18 in. On examining the reverse of this space, the damage found to have been inflicted by the six shots was considerably less than had been expected, no part of the iron being separated from the main body, and the cracks on the surface of the metal being very slight. During the past week a few steel and cast-iron spherical shot have been fired at one of the Millwall plates, that was tested some short time since, from the Armstrong 100-pounder smooth-bore lately forwarded from Woolwich to Her Majesty's ship "Excellent." As, however, the firing was limited, the results were comparatively unimportant.

The Board of Trade returns for the month of October are the most remarkable ever published, since they show an increase, wholly unprecedented, of 53 per cent. in the declared value of our exportations, compared with the total in the corresponding month of last year—the amount being £15,082,332 against £9,846,835, an excess of £5,235,497. Compared with October 1861, the increase is £3,397,422, or 29 per cent. The total of our shipments of cotton goods, exclusive of yarns, was £4,227,255, showing an increase of 140 per cent. in value, while the increase in quantity was 111 per cent. Of cotton yarn the total exports were £939,346, against only £266,693 last year. In haberdashery the increase has been 45 per cent.; in hardwares, 28 per cent.; in woollens, more than 40 per cent.; in linen, manufactures, 43 per cent.; and in machinery, 84 per cent. The exports of silk manufactures show a slight falling off. Of metals the quantities have been large in every instance, with the exception of lead. These extraordinary figures fully explain the then hidden causes of the constant absorption of gold for the purposes of internal circulation which was found to be taking place about eight or nine weeks back, and demonstrate the correctness of the supposition then expressed that some influences of an unusual character were in operation.

The new Admiralty night signals, introduced about two years ago by Mr. W. H. Ward, were tested on Tuesday night at the flagstaff in Woolwich dockyard, in the presence of the Commodore-Superintendent, Sir F. Nicolson, C.B., and other officers, in pursuance of instructions transmitted by Lord C. Paget, Secretary to the Royal Navy. The signals since their introduction have been in general use throughout the Mediterranean and Channel squadron. Mr. Ward has now suggested a slight improvement in the hoisting apparatus, in order to accelerate the issuing of signals and the facility of replying. The improvement consists of one hoist to each signal, which appears to save considerable time in the operation. A number of messages were transmitted through the fog, and the signals were witnessed on the river by Sir F. Nicolson, who went down in his gig for that purpose, his position being made known by one of the signal lamps placed in the gig, and with which the signals were answered. One person took charge of the signal station and assisted the inventor in operating, which was done with the same facility as with the flags by day. By the improved arrangement the work lines are dispensed with, and the system is pronounced materially benefited and simplified. The lamps used were the small models employed by the Channel fleet in August, 1860.

Patents for Inventions.

ABRIDGED SPECIFICATIONS OF PATENTS.

The Abridged Specifications of Patents given below are classified, according to the subjects to which the respective inventions refer, in the following Table. By the system of classification adopted, the numerical and chronological order of the specifications is preserved, and combined with all the advantages of a division into classes. It should be understood that these abridgements are prepared exclusively for this Magazine from official copies supplied by the Government, and are therefore the property of the Proprietors of this Magazine. Other Papers are hereby warned not to produce them without an acknowledgement:—

Boilers and Furnaces—*none*.
Buildings and Building Materials, 1073, 1096.
Chemistry and Photography, 1021, 1036.
Cultivation of the Soil, including agricultural implements and machines, 1022, 1033, 1042, 1058.
Electrical Apparatus, 1069.
Fibrous Fabrics, including machinery for treating fibres, pulp, paper, &c., 1038 1037, 1056, 1057, 1061, 1064, 1070, 1074, 1075, 1079, 1085.
Food and Beverages, including apparatus for preparing food for men and animals, 1040, 1083.
Furniture and Apparel, including household utensils, time-keepers, jewellery, musical instruments, &c., 1026, 1027, 1046, 1047, 1048 1050, 1068, 1077.
General Machinery, 1029, 1032, 1045, 1060.
Lighting, Heating, and Ventilating, 1031, 1041, 1065.
Metals, including apparatus for their manufacture, 1024, 1025, 1053, 1059, 1063.
Miscellaneous, 1020, 1030, 1044, 1049, 1066, 1067, 1071, 1072, 1078, 1082, 1084.
Roads and Vehicles, including railway plant and carriages, saddlery and harness, &c., 1035.
Ships and Boats, including their fittings 1034, 1055, 1080.

Warfare, 1023, 1043, 1051, 1062, 1081.

1019. J. Knowles and S. Jackson. *Certain Improvements in apparatus for heating water in furnaces, flues, and chimneys.* Dated April 24, 1863.

Provisional protection has not been allowed for this invention.

1020. R. Lavender. *A new compound to be used as a lubricator.* Dated April 24, 1863.

In carrying out this invention, the patentee takes ten parts of the hydrocarbonaceous material known as paraffin oil, of any density best suited for the especial compound; he then adds to it one and a half parts of common gum resin, or any of the resinous gums that are soluble in the above material. These two are mixed together by heat or otherwise, and after being properly united, he takes lime water up to the point of saturation (or any of the alkalies which will cause saponification) and adds it to the above compound, stirring or agitating it in such a manner as to bring it into contact with the alkaline properties, thereby saponifying the mixture to any degree he may deem necessary. These materials, when chemically united, form an unctuous compound, that is well suited for all purposes of lubrication. *Patent completed.*

1021. P. Passavant. *Improvements in the manufacture of blue colouring matter, and also of violet colouring matter.* (A communication.) Dated April 24, 1863.

In manufacturing this blue colouring matter the inventor takes four parts of fuchsine, eight parts of aniline oil, and two parts of acetate of soda, and heats this mixture slowly to 160 deg. Reaumur, at which temperature he keeps it for two hours, when he raises the same to 200 deg. Reaumur, again maintaining that heat for two hours. As soon as the required shade is obtained, the mixture is taken from the fire, and poured into four parts of alcohol, to which are added twelve parts of muriatic acid, for the purpose of neutralizing the blue matter. When cooled, he obtains a hard brownish black substance, which is ground, and then boiled for a quarter of an hour in a quantity of water, with eight parts of sulphuric acid. This mixture is filtered, and the blue matter obtained is boiled twice in eight parts of muriatic acid, for the purpose of destroying the red tint which has remained more or less in the blue matter. After this operation, he washes the blue matter several times in warm water, until all vestige of acid has disappeared. When this mixture has been pulverized and dried, he pours on the powder ten parts of alcohol, and lets it stand a few hours, until all vestige of red colour has disappeared. He then filters the mixture, pulverizes and dries it, and the powder thus obtained is fit for dyeing purposes. He calls it Bleu de Nuit. *Patent abandoned.*

1022. J. Cornes and J. G. Davis. *Improvements in lawn-mowing, rolling, and collecting machines.* Dated April 24, 1863.

This invention consists in so constructing machines employed for the above purposes as to impart to them an undulating motion, by adapting springs to the axes of the revolving parts of the said machines; and, further, in combining revolving brushes therewith, one of the said brushes being fixed upon the axis of the small running wheels, situated at opposite sides of the framing of the machine, and resting upon the surface of the ground immediately in front of the revolving cutters, which are of the ordinary spiral form. This brush is intended to raise the blades of grass if laid, and present them to the cutters. The other brush above referred to is intended to lift the cut grass from the cutters, and assist in depositing the same in a box or receptacle fixed above the cutters, and in front thereof. Another feature in this invention consists in connecting the axis of the small running wheels and cutters before mentioned to two bent levers, mounted loosely upon another axle, the ends whereof revolve in bearings in the sides of the framing of the machine. Upon the middle of this axle a spur pinion is fixed, and gears into a spur wheel mounted loosely upon another axle, carrying the driving roller of the machine, which runs on the surface of the lawn in the ordinary manner. A further improvement in lawn-mowing machines consists in adapting helical springs around the axle of the aforesaid driving roller, which press against the clutch boxes, and thus keep them always locked with the driving spur wheel, thus dispensing with the necessity for keeping the clutch boxes pressed in gear by hand during the working of the machine. The patentees propose to throw the cluches out of gear by levers, and hold them so by pins when the cutters are not required to be in action. In connection with the bent levers before mentioned, and to the upper arms thereof, a rod is loosely connected by its ends, and at the centre of the said rod a screw nut is formed, which carries the screwed end of another rod extending horizontally at right angles to the former rod; this second rod is supported in a bearing at the hind part of the machine, and has a lever wheel fixed thereon for turning the screw round, by doing which the bent levers aforesaid, together with th

parts connected thereto, may be readily raised and lowered, and the cutters adjusted any desired distance from the surface of the ground. By these means, and by adjusting nuts placed upon the supports of the axis of the cutters and running wheels before mentioned, the said cutters may be set to a nicety, so as either to cut only the tops of the blades of grass, or cut it close, as may be desired. The cutters are driven by spur-gearing. There is a castor roller and handle connected to the front part of the framing of the machine, and there are also handles at the back of the machine. *Patent completed.*

1023. J. THOMPSON. *Improvements in the manufacture of barrels for firearms and other description of tubes, and in apparatus or machinery to be employed for that purpose.* Dated April 24, 1863.

This invention consists in making barrels for firearms without weld or joint, and with a solid breech; and also in making other descriptions of tubes which may require to have solid parts upon them. The patentee effects by means of rolls of peculiar construction, and by employing a thick solid tube or billet of metal, with a hole punched through it for the formation of such tubes. This billet or thick tube is first passed in a heated state (if the metal is of a kind to require heat) through preparing rolls of the ordinary construction, by which it is lengthened or drawn out, and it is then removed to rolls formed with a double collar in one or both sides of the groove, or with a collar and a bearing; a stop-piece is fitted into the groove, against which stop the roller places the end of the barrel or tube; this stop also acts as a guide to indicate when the barrel is to be put in the roller, and governs by its position in the rolls the length of the barrel or tube. At any suitable point in the periphery of the grooves of one of the rolls, a sinking is formed to shape the breech or solid part of the barrel or tube, and as the barrel requires turning in the direction of its circumference after every rolling an opening is cut through the bearing of the roll to admit the breech or solid part, which is thus forced against the roller and against the stop, and shaped. *Patent completed.*

1024. J. THOMPSON. *Improvements in machinery for punching metals.* Dated April 24, 1863.

This invention consists of improvements upon, or additions to, the steam hammer, for the purpose of adapting it to punching masses of steel, steel iron, iron, or other metals, to be subsequently manufactured into ordnance barrels for firearms, and various other description of tubes, and for other like uses. The patentee fits in the head of a steam hammer a suitable punch, and in the anvil a suitable die, having an aperture through the bottom to allow the plug struck out by the punch to pass through. A guide apparatus, consisting of slides upon the anvil, keeps the blank in position whilst it is struck by the punch. This guide apparatus is governed by four wheels, so that an attendant may release the blank after it is punched, by means of a lever below the anvil block, and throw it out of the die. The blank thus prepared is ready for rolling, drawing, or swaging into a tube which will have no joint. *Patent completed.*

1025. W. A. SHAW. *A mode of lining lead pipe with tin or its alloys.* Dated April 24, 1863.

This invention consists in the manufacture of lead pipe with a lining of tin, by forcing an ingot of tin and an ingot of lead while over a core out of a cylinder through a die by hydraulic pressure. *Patent completed.*

1026. J. HINKS and J. NEWMAN. *Improvements in the manufacture of buttons.* Dated April 24, 1863.

One portion of this invention consists in making buttons commonly called four-holed buttons, or brace buttons, and other buttons, in the following manner:—The inventors cut the blanks from which they make the said buttons from tin plate which has been planished by rolls, or by the process called wheeling, and afterwards polished and burnished, and they make up the buttons from the said blanks in the usual way. *Patent abandoned.*

1027. J. H. JOHNSON. *A filtering apparatus for treating by pressure oils, syrups, and all sorts of liquids susceptible of filtering.* Dated April 24, 1863.

This invention consists in the employment of a peculiar arrangement of apparatus for filtering liquids, whereby such operation may be effected under pressure. The liquid to be filtered is contained in a vessel or tank, to which a suction and force pump is connected, which pump is also in communication (by means of a pipe) with a strong filtering vessel. The filtering vessel is provided with a manhole at the top, and a grating at the bottom, upon which grating is placed the filtering medium, consisting of felt or other suitable material. Immediately beneath the grating, and secured to the filtering vessel or otherwise, there is fitted a hemispherical or other receiver, in which the filtered liquid is collected and drawn off by a central pipe and stop cock. The liquid to be filtered is pumped into the filtering vessel, and the pumping is continued after such vessel is full, in order that the liquid therein may be in a state of compression, which state facilitates and expedites the process of filtering by forcing the liquid through the filtering medium. In some cases this apparatus may be employed as a press—as, for example, by introducing olives into the filtering vessel, and injecting and forcing therein under considerable pressure hot water, the oil will be expressed, and thus the double effect of the press and the filter or purifier is obtained. *Patent completed.*

1028. C. POOLEY. *Improvements in certain parts of machinery for preparing and spinning cotton and other fibrous substances.* Dated April 25, 1863.

This invention is applicable to all machines in which drawing and calender rollers with top rollers are employed, and it consists in an improved mode of constructing the weight hooks and saddles to which the ordinary weights are suspended. It has heretofore been customary to make a hole in the weight hooks and saddles through which the oil is poured for lubricating the top roller. Now, this invention consists in making the weight hooks and saddles with recesses or chambers containing a wad of felt, or other suitable material, saturated with oil or other lubricating compound, which, as the top roller revolves, passes through small holes at the bottom of the recesses or chambers, and thus lubricates the top rollers. Another part of the invention consists in suspending the weight hook to a projection within the saddle, which is made broader than usual to reduce friction. *Patent completed.*

1029. L. DE BREANSKI. *Improved apparatus for fixing drills, which invention is also applicable for fixing apparatus for raising, supporting, and suspending weights, and for other analogous purposes.* Dated April 25, 1863.

The chief object of this invention is to provide a means for applying drills to the drilling holes in metal plates or beams when fixed in a position more or less vertical or perpendicular—for example, in framing and plates of iron ships, boilers, bridges, and other structures. In effecting this object, the patentee provides the drill with a ratchet lever, crank, or winch handle, and mounts it in an adjustable holder, using as a purchase or support of the drill holder, at any desired part of the plate or other surface to be drilled, a modification of what are known as "pneumatic bells," consisting of a metallic bell or cup closed by a disc or plate of vulcanized india rubber, or other suitable elastic material, which acts as an exhausting piston, and forms a partial vacuum between the bell and the surface to which it is applied, so that the requisite amount of adhesion is obtained by atmospheric pressure to resist the pressure of the drill and support the parts in position that carry the drill. *Patent completed.*

1030. S. HARRISON. *A new and improved mode of manufacturing type for letterpress printing.* Dated April 25, 1863.

At present the usual mode of manufacturing type is by casting one letter or type at once. This invention consists in casting a number of types, say, from 10 to 100 at once, and then cutting, breaking, or sawing them into separate letters or types. *Patent completed.*

1031. A. H. CLARK. *Improvements in valves for water, steam, and gas.* Dated April 25, 1863.

According to this invention, the inventors make the seat of the valve in a plane in which the axis of the pipe is situated, the ingress and egress pipes being placed on either side of, and opening respectively above and below, the said seat. The valve rises and falls in a line at right angles to the axis of the pipe. The said valve is fitted to a stem or axis, the upper part of which is made into a screw. The lower cylindrical part of the said stem or axis passes through a stuffing box, which is fixed upon and closes the opening in the pipe at which the valve is introduced. The upper screwed portion of the stem or axis works in a concave screw in the plate closing the top of the stuffing box. By means of a winch or handle on the top of the valve stem or axis, the said stem or axis can be turned and the valve raised or lowered. The height to which the screw is raised out of the stuffing box indicates the height to which the valve is raised from its seat. The gland by which the packing is compressed around the cylindrical part of the valve stem is held down by screws engaging in the top of the stuffing box. *Patent abandoned.*

1032. T. A. WESTON and C. VIVIAN. *Improvements in pulleys, capstans, and other machines for raising weights and transmitting motive power.* Dated April 25, 1863.

This invention comprises certain means for holding the rope, chain, or band firmly on the pulley, capstan, or other machine during the time the said rope, chain, or band is passing over the pulley, or other machine, and communicating motion thereto, or receiving motion therefrom. *Patent abandoned.*

1033. J. P. and E. B. NUNN. *Improvements in hoes and cultivators.* Dated April 25, 1863.

This invention consists in the employment of a circular disc or polygon, with the cutting edge or edges placed horizontally, or at a slight angle to the horizon, and fitted on the lower end of an upright shaft, free to revolve, and also to rise and fall within certain limits in a tube or tubular bearing fixed in or connected to a beam. Upon the implement being drawn or propelled through the soil, the cutting disc will be caused to revolve, when the pressure on one side is greater than that on the opposite side, thus preventing any accumulation on the cutting edge or edges. *Patent completed.*

1034. J. DUNBAR and J. W. WOODFORD. *Improvements in apparatus for steering and manœuvring ships and vessels.* Dated April 25, 1863.

For the purposes of this invention, an upright shaft or axis is applied at or about the centre or midships of a ship or vessel, the lower end of which passes through the bottom, and has affixed to it radial blades or vanes which come just below the bottom of the ship or vessel, or within a recess formed in the bottom. The upright shaft or axis passes within a tubular passage fixed within the ship, which rises to a height sufficiently above the water line; or a suitable stuffing box or other provision is to be made in order that no water may get into the ship or vessel, and when desired the shaft or axis may be raised in order that the vanes or blades may be replaced. The shaft or axis is acted on by steam or other power to give rotary motion thereto, in order that the axis or shaft, and the blades or vanes fixed thereto, may be caused to rotate towards the right hand or to the left, according to the direction in which it is desired that the vessels should be steered. *Patent completed.*

1035. L. A. J. BRUET. *Improvements in apparatus for registering, indicating, and verifying the time and distance passed over by vehicles, also applicable to machinery and other similar purposes.* Dated April 25, 1863.

This invention consists—1, in a method of indicating whether the vehicle is disengaged or employed; 2, in showing the distance travelled over, and the time the vehicle has stopped, calculated or represented in distance; 3, in a mode of marking, indicating, and verifying or proving the work performed by the vehicle or machine. A suitable external sign is placed on the front and top of the case of the mechanism, or on the driver's box, for indicating that the vehicle is disengaged or not hired. But when a fare is taken, the driver turns a handle a quarter of a circle, causing thereby the external sign to be lowered, and to disappear, and at the same time to actuate the gearing required for the motion of the apparatus or mechanism of the distance index. The handle in turning performs three separate operations. The first shows that the vehicle is not hired; the second, or first turn of a quarter of a circle, shows that the vehicle is hired by the mile—that is to say, the distance run over, to which may be added the time of the stoppages, represented by the proportional mean of the distance (calculated at about 5 miles per hour); the third operation indicates the slow motion of the vehicle—that is to say, that independently of the velocity of the vehicle, the mile or distance index will constantly indicate a mean velocity of the vehicle when in motion, and its stoppages. By these means only one tariff per mile for all cases is required. When the fare leaves the vehicle, the handle is returned to its rest mark, the mileage index hand returns to 0, and the internal sign reappears. All these operations shown to the fare or traveller are written or marked on an internal plate or dial; also the time of each of these operations. *Patent completed.*

1036. A. POIRRIER and C. CHAPPAT. *Improvements in the manufacture of blue and violet colouring matters, suitable for dyeing and printing.* Dated April 25, 1863.

For the purposes of this invention the patentees take the aniline reds (known in commerce under the names of fuchsine, roseine, magenta, and under other names, and chemically as being different salts of rosaniline), and they treat these red colours with napthylamine—a substance which is derived from napthaline, as aniline is derived from benzine. *Patent completed.*

1037. F. WALTON. *Improvements in the manufacture of fabrics for covering floors and other surfaces, and in the apparatus employed therein.* Dated April 25, 1863.

For the purposes of this invention, canvas, or other suitably strong fabric, is coated on its upper surface with a composition consisting of oxidized oil (prepared, by preference, in the manner described in the specification of a patent, granted to the present inventor the 27th January, 1860, No. 209), cork dust, and gum or rosin, preferring gum kaurie, or New Zealand gum; such surface being afterwards printed, painted, embossed, or otherwise ornamented. The back or under surfaces of such fabrics are coated with a coating of such oxidized oils, or oxidized oils and gum or rosin, and, by preference, without any admixture of cork. *Patent abandoned.*

1038. O. BEYER. *Improvements in safety valves.* (A communication.) Dated April 25, 1863.

It is well known that the common or ordinary safety valve, when loaded to counterbalance a given pressure of steam, does not lift or blow off freely until the pressure has increased to a considerable extent above the pressure fixed upon; consequently, the boiler is but slowly relieved of the excess of pressure owing to the small area of the opening of the valve. The object of this invention is wholly or partially to remove this defect, by causing the safety valve, when the pressure has become sufficient to overcome the weight upon it, to lift much higher than the ordinary safety valve, and thus give a larger opening for the escape of the steam or other fluid; and the invention consists in forming a flange round the valve, commencing at the inner edge of the valve facing, which is undercut and concave in shape, and the concave side is towards the seating of the valve, which has also a flange upon it, commencing at the outer edge of the valve seating; but the upper surface of the flange is convex, and corresponds nearly to the concave surface of the flange upon the valve. There is a slight space between the concave and convex surfaces of the two flanges, which diminishes towards the outer edge of the flanges. When the steam begins to escape from between the surfaces of the valve, it gets between the concave and convex surfaces of the two flanges, and its force thus acts upon a larger area, and reacts upon the concave surface of the valve, and causes it to open to a greater extent than the ordinary safety valve. *Patent completed.*

1039. I. DIMOCK. *Improvements in machinery for cleaning, sorting according to size, and doubling silk and other threads.* Dated April 25, 1863.

The patentee claims—1, the system or mode described of cleaning and sizing threads at the same time; also, the system or mode described of cleaning, sizing, and doubling at the same time. 2, the use of wedge-shaped spaces for sizing threads, and arrangements for varying the position of the thread or threads to be sized in such spaces, as described. 3, the use of a piston or its equivalent in connection with oscillating, gauging, or sizing mechanism, to moderate or prevent irregularities, as described. 4, the use of stopping arrangements in connection with mechanism for sizing threads, acting in the manner described. 5, the system or mode of doubling two threads, as described. 6, the method and arrangements for unwinding sized thread, as described. *Patent completed.*

1040. A. LEGRAS. *Improvements in machinery or apparatus for making ices.* Dated April 25, 1863.

According to this invention, one or more freezing apparatus are actuated by means of driving bands or gearing from one driving shaft common to all, provided with suitable clutches, whereby the working of any one or more of the apparatus may be arrested without interfering with the working of the rest. Each freezing apparatus consists of an outer fixed tube or vessel, in which rotates a metal cylinder, supported upon a footstep bearing in the bottom of the outer vessel. A vertical spindle passes up the centre of the metal cylinder, and is supported at the upper end by a suitable bracket piece, fitted into a socket in the edge of the tube. The cylinder is closed at the bottom and open at the top, its mouth being level with the top of the outer tube or vessel. Round the mouth of the cylinder there is soldered a metal collar, round which the strap or driving band passes, slots or openings being made in the side of the outer vessel for the strap or band to work through. The freezing mixture is introduced into the outer vessel or tube, and the

cream or other ingredients to be manufactured into ice are contained in the metal cylinder, or inner rotary vessel, an annular lid or cover being placed over the tube, so as to cover the mouth of the same, and leave the mouth of the cylinder open. *Patent completed.*

1041. J. T. STROUD. *Improvements in the manufacture of, and in the machinery and appliances for, holding, drilling, turning, tapping, fitting and shaping certain parts of steam, water, gas, and lamp fittings.* Dated April 25, 1863.

Provisional protection has not been granted for this invention.

1042. W. E. NEWTON. *Improvements in thrashing machines, parts of which improvements are also applicable for hulling, decorticating, cleaning, and polishing grain and seeds.* (A communication.) Dated April 25, 1863.

The patentee claims—1, the thrashing, decorticating, and cleaning of grain or seeds by passing them between two cylinders, in the manner and for the purpose set forth; 2, grooving or fluting one of the cylinders, the other being covered with an elastic substance, such as caoutchouc; 3, driving the cylinders at different speeds; 4, the general arrangement of apparatus. *Patent completed.*

1043. A. V. NEWTON. *Improvements in breech-loading firearms.* (A communication.) Dated April 25, 1863.

This invention is not described apart from the drawings. *Patent completed.*

1044. M. BARLAND. *An improved apparatus for milking cows.* (A communication.) Dated April 25, 1863.

Provisional protection has not been granted for this invention.

1045. S. OSBORNE. *An improved machine for unwinding crinoline steel.* Dated April 27, 1863.

This invention consists in placing a piece of wood, or any other suitable material, above and parallel with the roller, the ends of which parallel piece are to slide in grooves in the uprights which support the roller, and to be acted on by a spring or springs, so placed as to press the parallel piece towards the roller. The invention also further consists in a piece of brass or any other suitable material passing down each side of the roller, and through the parallel piece above the roller, and made moveable by a screw to suit any steel which may be put on the roller; the steel on the roller is kept on the one side by the upright, on the other by the brass, and above by the parallel piece; and thus prevented from springing about in any way, and by means of a handle placed to the roller, the crinoline steel can be rolled off or on at pleasure. *Patent abandoned.*

1046. G. SPILL, T. J. BRIGGS, and D. SPILL. *Improvements in the manufacture of mill straps and driving bands.* Dated April 27, 1863.

This invention consists in imbuing wool, woolly substances, cotton, linen, jute, flax, or any fibrous substance (either in the form of prepared fabrics, or in the form of warps, wefts, or any other form whatever) with glue, gelatine, or any gelatinous substance, either animal or vegetable, and from whatever source derived. These matters are to be combined with the above-named materials either in the wefts, warps, or webs, or in the actual process of fabrication. The precipitating of the gelatine into the body of the said materials or substances is effected by any astringent substance, such as sulphate of alumina, catechu, bark, gallic acid, or gallate of iron, and the impregnation of the same by any metallic base or bases. The inventors also imbue the aforesaid fibrous substances with india rubber, or any compound thereof. *Patent abandoned.*

1047. H. E. CARCHON and E. F. RAYBAUD. *Improvements in the manufacture of hats and bonnets, and mode of preparing feathers to be used in the said manufacture.* Dated April 27, 1863.

This invention consists in substituting the outer covering or surface of the backs of the stems of feathers for the straw and other materials at present employed in the manufacture of bonnets, hats, crinolines, and other similar articles, where lightness, elasticity, and durability are required. The mode of preparation is extremely simple. The back of the feather being the most suitable part, it is carefully stripped off and cut the length and thickness required; thus prepared, it is plaited and made up in the same way as straw, to which, from its elasticity, it is infinitely superior. *Patent completed.*

1048. J. J. ROBERT. *Improvements in the manufacture of spoons and forks.* Dated April 27, 1863.

This invention consists in covering with an extra coating of silver those parts of forks and spoons most exposed to wear. *Patent completed.*

1049. W. E. GEDGE. *Improvements in tuyeres or blast pipes and in apparatus connected therewith.* (A communication.) Dated April 27, 1863.

The tuyere or blast pipe, made according to this invention, is provided with a regulator for the escape of the wind, and a balance compass for opening the outlet pipes without disturbing the symmetry of the fire. This compass or double lever may be applied vertically in the side of the furnace, or horizontally on its face. The moderator or regulator with which it is provided consists of a moveable washer, which, on the handle of the moderator being pulled, partially or entirely closes the pipe at will. A revolving door for delivery of coal, and a lubricating or grease pipe also forms part of this apparatus. In the thickness of the tuyere cap (which is then of semi-spherical shape) may be made an excavation, into which water will be brought by a pipe connected with the lower ring of the tuyere. *Patent abandoned.*

1050. M. VALKENHUYZEN. *A new castor for furniture.* Dated April 27, 1863.

The patentee claims—1, the use of a double plate to constitute the system of rotation; 2, the use of a double circular groove corresponding between the two plates, to serve as channel for the rotating balls or beads; 3, the use of loose balls or beads of hard material rolling in the circular groove between the two plates; 4, fixed rivetting of a rod or stem more or less long in the upper plate, and loose rivetting of the same in the lower plate, to facilitate the movement of the cheeks or cap in every direction; 5, the nearly vertical cheeks or cap forming one piece with the lower plate. *Patent completed.*

1051. W. RICHARDS. *Improvements in ordnance firearms and cartridges.* Dated April 27, 1863.

In constructing ordnance according to this invention, the inventor employs an inner tube or liner, and he shrinks or forces on to this exterior rings or tubes, as has heretofore been practised. The inner tube or liner he makes of steel or iron, faced interiorly with steel, in order that it may be less liable to wear, or be injured in fixing, than if it were of iron; and, further, for the purpose of ensuring that the inner tube or liner shall be efficiently supported by the exterior ring or tubes, he splits the tube or liner from end to end, before the exterior rings or tubes have been shrunk or forced upon it, and he prefers that this split should follow one of the grooves in the rifling of the piece, and that it should be inclined at a considerable angle to a radius of the bore. By this arrangement the inner tube or liner will be rendered capable of expanding slightly, and nearly the whole strain of the explosion will fall on the exterior rings or tubes, even should these not be perfectly fitted. In constructing the barrels of fowling-pieces and similar firearms, he employs a thin steel tube, and he cases the breech end thereof with iron, in order to give to it the strength required to resist the strain of firing; but the end of the tube which forms the muzzle of the barrel he leaves uncased, as it will not be exposed in firing to a sufficiently severe strain to render this necessary. He cases the breech end of the steel tube by lapping a band of iron around it, and adding it to the tube. In this manner he obtains a light and safe barrel, with an interior surface of steel, which is not so liable to rust, and is less subject to wear than an ordinary wrought-iron barrel. In making cartridges for breech-loading fowling-pieces, he places at the back of the case of the cartridge a wad, which is saturated with wax, or other material. The wad has a small hole formed in it, and a tube or long capsule is passed through it; the tube or capsule is conveniently made of thin copper, and is charged with fulminating material. At the back of the cartridge, and behind the wad, a pin passes through the side of the cartridge, and its lower end rests on the exterior of the tube or capsule containing the fulminating material. When the capsule is placed in the gun, and the gun is fired, the hammer strikes the pin, explodes the fulminating material, and ignites the powder at the front end of the tube or capsule. *Patent abandoned.*

1052. J. JEFFREYS. *Improvements in constructing surface condensers, and apparatus for heating and cooling fluids.* Dated April 27, 1863.

This invention consists, mainly, in constructing surface condensers of steam engines with thin plates of copper, or other metal, which the inventor presses or stamps with numerous parallel flutes; separated the one from the other by flat ridges. These plates are then placed together in pairs, face to face, so that the ridges of one plate come truly over those of the other, but they are separated by a soldering or brazing metal placed between the two. The pairs of fluted plates thus arranged are piled up one pile over the other, but with suitably-fluted plates of iron between the pairs, so as to make a solid pile, which is then placed under pressure to bring the ridges of the two plates of each pair close up the one to the other; in this state the pile is heated till the soldering or brazing melts, when the plate still under pressure, or placed if necessary under increased pressure in a press, is allowed to cool. *Patent abandoned.*

1053. F. BENNETT. *An improved method of condensing lead and other metallic fumes and vapours from furnaces.* Dated April 27, 1863.

This invention has for its object the condensation of the metallic fumes of lead, copper, and other ores and minerals, also noxious smoke and gases, salts, acids, and other vapours volatilized from smelting and other furnaces. The patentee places a wheel, by preference constructed on the principle of the archimedian screw, or any other form of wheel, with vanes or floats in the main flue, or in a separate chamber arranged for the purpose, through which all the waste or volatilized metallic fumes, smoke, gases, salts, acids, and vapours to be condensed are passed; and he causes a constant supply of water to be maintained at such a level in the chamber or flue that the ends or more of the vanes may be immersed. He imparts rapid rotary motion to the wheel, when the metallic fumes and other products are drawn and thrown to the periphery; the vanes at the same time throw a constant spray or quantity of water, which, mingling with the fumes and other products, condenses them. Should perfect condensation not be effected by one wheel, a second wheel or more may be employed in the same flue or chamber, or in similar flues or chambers, and the process repeated over and over again until entire condensation is secured. *Patent completed.*

1054. R. A. BROOMAN. *Improvements in twisting and doubling silk, and in frames employed therein.* (A communication.) Dated April 27, 1863.

To overcome the many disadvantages arising from the use of separate frames or machines, the inventor has devised a method of effecting the most simple preparation of silk upon one frame, and at one operation, and the most complicated preparations upon one frame at one time, the winding not being included—that is to say, that the first torsion, the second torsion, and the doubling are simultaneously effected by one single operation. A frame fitted according to this invention, unites and combines in one single operation three operations which heretofore necessitated as many frames. With the exception of the winding, he performs upon the same frame, and at the same time, the first and the second torsion, as well as the doubling, when the two torsions are necessary. *Patent abandoned.*

1055. W. H. JAMES. *Improvements in indicating the locality of fire, applicable also to denoting the position of ships.* Dated April 27, 1863.

This invention consists in the combined employment of a spy-glass or telescope from a fixed tower, and of a map of the city, town, or locality within the range of a telescope from the point of observation, and in causing a tracer to travel with the motions of the telescope, and indicate on a map the spot at which the object observed is situated. The inventor takes his observation from a high tower, and places the observing glass in a frame free to move horizontally and vertically; he connects this frame by rods with a tracer which partakes of similar motions to those of the frame; and, according to the angle and the position of the glass, so the tracer indicates the spot on the map of the object observed. *Patent completed.*

1056. W. HUDSON. *Improvements in looms for weaving.* Dated April 27, 1863.

This invention is not described apart from the drawings. *Patent completed.*

1057. A. ROLLASON. *Improvements in dyeing and staining fabrics, parts of which improvements are also applicable for dyeing, staining, and ornamenting glass and other substances.* Dated April 27, 1863.

This invention relates, in the first place, to a mode of dyeing or staining woven fabrics or paper that have been rendered waterproof by being coated with solutions of pyroxyline, either alone or mixed with oils, gums, rosins, or other suitable substances, which are capable of combining or being mixed with volatile, ethereal, or spirituous liquids. The fabrics having been coated in the ordinary or any convenient manner with the waterproofing liquid, may be dyed or stained of various shades of colour, by simply applying a methylic, alcoholic, or ethereal solution of the desired colour to the surface to be operated upon. Aniline colours, or colours obtained from coal tar, are the colours the inventor usually employs. *Patent abandoned.*

1058. H. BEARE. *Improvements in machinery for thrashing out corn from its straw, part of which is applicable for combing the straw.* Dated Aprill 27, 1863.

According to these improvements, the patentee uses a cylinder, on which he places the teeth or radial pins, and distributes them uniformly throughout its entire length and periphery. They may be set in spiral or helical lines, or otherwise, but in either case should have very few teeth engaging in the corn at one time. This apparatus is also used for thrashing out the corn and combing the straw for thatch and other purposes. In thrashing machines in which the straw is allowed to pass through and the winnowing conducted at the same time, he applies a feeding apparatus consisting of radial teeth on a drum, reel, or cylinder, such as before described, which takes up the corn to be thrashed and feeds or supplies it to the machine, which it does in a regulated and efficient manner, although the sheaves or parcels of corn may be thrown in by the attendant indiscriminately. To facilitate the feed, he mounts over this rotating toothed feeder a concave surface; this leads the corn into the concave and beater below, into which it passes, and is acted on in the ordinary way. The feeder may be used at the same time as a comber. The feeder has rapid rotary motion communicated to it by a strap from the driving-gear of the machine, which is driven by horse or steam power, as usual. *Patent completed.*

1059. S. INGLEDEW. *Certain improvements in obtaining iron from its ore, and in the subsequent treatment thereof, for converting the product into a metallic state, and in apparatus connected therewith.* Dated April 28, 1863.

This invention consists, first, in reducing the ore by grinding or pulverizing in an ordinary grinding apparatus, or one suitably arranged for the purpose; it is then to be placed in a perforated rotating chamber or receptacle, through which water passes, wherein the heavier particles of granulated metal are precipitated by gravity to the bottom, the lighter earthy and other matters being carried off by the water. This residuum of wasted granulated iron ore (which still retains a small quantity of silica and silicate of potassium), is then conveyed to an open flat vessel or drying frame, where the moisture is evaporated therefrom, and it is afterwards passed into an ordinary air or reverberating furnace, by which it is reduced to cast metal. *Patent abandoned.*

1060. J. and W. MARRIS. *An improved machine for breaking loaf sugar.* Dated April 28, 1863.

This invention consists of two metal frames, about 4 ft. high and about 2 ft. wide, and two circular saws, one 24 in. in diameter, and the other 13 in. in diameter, fixed one inside and the other outside these frames, and working on a spindle, and two pair of metal rollers with steel knives fixed underneath the spindle. The advantages of its use are, among others, a great increase of amount of sugar cut by the same power. The sugar retains its clean white appearance, because it is not handled as when hand cut, and the crystal hue fracture of the cubical lumps is preserved in brilliancy, because the sugar is broken or chopped and not sawed. *Patent completed.*

1061. S. CRABTREE. *Improvements in balling [illegible].* Dated April 28, 1863.

This invention consists in forming balls of slivers of wool, or other fibrous materials or wa[illegible] in such a manner that, when in course of the succ[illegible]ons these balls are placed to be worked up[illegible] following each other in the processes [illegible]her fibrous materials or warps, the s[illegible]n out from the inside of the said bal[illegible] the said sliver or warp has had hith[illegible]hus a considerable advantage gain[illegible]ers of wool or other fibrous mate[illegible]atentee effects this by drawing off the [illegible]nside of the [illegible] through the cir[illegible] of [illegible] the ends, as hit[illegible] middle of the [illegible] usually forme[illegible] barrel, tube, [illegible] sliver or war[illegible] fastened a[illegible] groove in [illegible] or spindl[illegible] usual [illegible] through [illegible] or war[illegible] upo[illegible]

inside through the circumference, by which means the sliver is made to come out from the ball perfectly straight and open. *Patent completed.*

1062. G. HALL and J. WELLS. *A new explosive compound applicable for all the purposes for which gunpowder is, or may be, used.* Dated April 28, 1863.

This invention consists in producing an explosive compound, for general purposes, of the following ingredients, slightly modified according to requirements—say, in the proportions of 100 :—The patentees take 47 parts of chlorate of potassa, 38 parts of ferrocyanide of potassium, together with about 5 parts of sulphur, or other chemical, such as refined sugar, which they have found to be preferable from two causes—1, it is less detonating or liable to explode from mere friction; and, 2, more perfectly explosive, leaving no deposit or fouling. They reduce these ingredients separately to a powder by grinding in a suitable mill, or otherwise, and when the ingredients are properly ground, they are to be thoroughly mixed, adding water or nitric acid diluted with water, which increases the strength, imparting to the compound a bluish green colour, and is readily taken up and incorporated with the other ingredients to permit the whole to be formed into a stiff paste; afterwards, they allow the composition thus prepared to stand, allowing the water used to evaporate, and then they add 10 parts of caoutchouc slightly incorporated with bisulphide of carbon, which has the effect of destroying any impurity in the general compound, so that there shall be less residue after the explosion. These ingredients must be thoroughly mixed one with the other, and if to be used in the form of powder, must be pressed and then granulated fine or coarse, as preferred, or according to the purpose for which it may be required to be used. *Patent completed.*

1063. A. KINDER. *Improvements in the manufacture of sheet metal, and in ingots or plates of metal, and in the machinery or apparatus employed therein.* Dated April 28, 1863.

This invention relates, partly, to a peculiar combination and arrangement of rolls and apparatus connected therewith, to be employed in rolling sheet lead or other soft metal, whereby the adhesion of the sheet metal to the rolling surfaces is prevented, and a better and more even sheet is obtained. *Patent completed.*

1064. W. CLARK. *Improvements in machinery for the manufacture of paper and of the various kinds of boards produced from fibrous substances.* (A communication.) Dated April 28, 1863.

This invention consists, principally, in the combination and arrangement of two or more cylinder moulds in such manner as to deliver their webs of pulp one upon anothtr, for the purpose of being pressed together to form a board of a required thickness, and in the arrangement of drying and calendering apparatus for drying and calendering such board while in a continuous length, and before it is cut into sheets, so that the board is made and finished ready for the market by one continuous operation. The same arrangement of machinery may, by very slight additions, be adapted for the manufacture of several distinct and separate webs of paper at the same time. *Patent completed.*

1065. G. W. FULLER. *A new and useful or improved submarine lantern to be used in explorations beneath the surface of the ocean or any other large body of water.* Dated April 28, 1863.

This invention consists in producing a lantern which, when in use at whatever depth below the surface of the sea or a body of water in which it may be immersed, will have a pressure of air within it equal or about equal to the pressure of the water on its external surface, thereby enabling the patentee to construct a lantern of little strength and weight comparatively, one easily handled by a marine driver while in the water and below the surface thereof. *Patent completed.*

1066. J. H. JOHNSON. *Improvements in drying and cooling grain, and in the machinery or apparatus employed therein.* (A communication.) Dated April 28, 1863.

This invention relates to a mode or method of drying and cooling grain by the action of hot and cold air in suitable apparatus, and consists in the employment for the purpose of a box or kiln provided at its upper portion with a perforated metal, or with a web of fine wire-work, which extends over the entire area of the box or kiln, with the exception of a small slit or opening at one end of the box or kiln through which the dried grain escapes to the cooling apparatus. This perforated metal plate or wire-work is corrugated longitudinally, so as to form a series of parallel troughs or channels of a semicircular section, within each of which channels or troughs works an archimedian screw, or a shaft provided with a number of inclined blades, their object being when rotated to carry the damp grain along the perforated or reticulated surface. By making this surface in the form of a series of troughs, the hot air which enters below the same can penetrate the passing grain from the bottom and sides simultaneously, and so expedite the drying process. *Patent completed.*

1067. J. H. JOHNSON. *Improvements in apparatus for preserving property in case of shipwreck.* (A communication.) Dated April 28, 1863.

In carrying out this invention, it is proposed to construct the bag intended for the reception of letters or parcels of india rubber, gutta percha, or other flexible waterproof and air-tight mateaial suited for the purpose, and to rivet to each side of the mouth of this bag a metal jaw, the series or row of rivets extending not quite the entire width of the bag or length of the bar, so that the mouth may be readily opened for the introduction and removal of its contents. The jaws are rebated on the inner sides to accommodate the extra thickness of the material composing the bag at that part, and the inner heads of the rivets are covered by a strip of waterproof material to form a tight joint when the bag is closed. According to one mode of securing these jaws in a closed position, it is proposed to employ two or more swivel screw-bolts passing through both jaws, one of which swivels is provided with a locking arrangement for securing the bolt. *Patent completed.*

1068. G. S. MACDONALD. *Improvements in card-cases.* Dated April 28, 1863.

This invention consists in a method of constructing card-cases, whereby the card can be withdrawn without opening the case. *Patent abandoned.*

1069. T. MOORE. *Improved apparatus for laying down, protecting, and controlling submarine cables for telegraphing from vessels moored off a coast to the shore.* Dated April 28, 1863.

This invention is not described apart from the drawings. *Patent completed.*

1070. R. BUTTERWORTH. *Certain improvements in carding engines to be employed for carding cotton and other fibrous substances.* Dated April 28, 1863.

This invention relates to that part of the carding engine known as the stripper, and is employed to strip the "fleece" or sheet of fibrous material fsom the "doffing cylinder." The invention consists in the employment and use of an internal shaft, having a number of pins or points arranged in several spiral lines or otherwise upon its periphery, and in enclosing such pins within a cylindrical casing, excepting at the point where they are required to protrude to strip the doffing cylinder, such casing being perforated with holes corresponding to the pins through which they emerge and retire. This exterior casing is placed eccentrically from the internal central shaft, its ends working on eccentrics, and it is also provided with an internal ring of teeth, taking with a pinion on the said shaft. The casing being thus driven by a band and pulley, causes the rotation of the shaft, both revolving together, but eccentrically to each other, which causes the pins to emerge in succession from the perforations at a certain point of the revolution to strip the fibrous matter from the "doffer," and to retire again within the cylinder, cleansing themselves against the sides of the perforation. *Patent completed.*

1071. G. DAVIES. *An improved machine for agitating and mixing substances.* (A commnnication.) Dated April 28, 1863.

This invention consists of two or more spiral or twisted rods or bars contained in a vessel of suitable form, one spiral rod being left-handed, and the other right-handed, or the rods being otherwise so formed and arranged and caused to so revolve as to produce separate currents in, and a thorough agitation and admixture of, the contents of the vessel. *Patent completed.*

1072. G. E. DONISTHORPE. *Improvements in apparatus used when getting coal and other minerals.* Dated April 28, 1863.

When using a carriage with picking or other cutting apparatus mounted thereon for getting coal and other minerals, it has been usual, in order to resist the vibration consequent on the regular successive impacts or actions of the picks or other cutting tools, to make the carriage of considerable weight; and the object of these improvements is to obtain the requisite stability and capability to resist vibration when a light carriage is employed. This it is propðsed to accomplish by applying a wheel or wheels to the carriage to act against the roof of the working, in addition to the wheels which rest on the rails or ways on which the carriage is moved from place to place, and such additional wheel or wheels is or are pressed elastically against the roof of the mine. This is most conveniently done by means of a piston in a cylinder containing compressed air, acting directly or by interposed levers on the axis of the wheel or wheels in contact with the roof; or other suitable means of obtaining the requisite pressure may be resorted to. *Patent completed.*

1073. H. Y. D. SCOTT. *Improvements in the manufacture of cementitious substances.* Dated April 28, 1863.

The patentee claims—1, subjecting the calcined mineral to the action of steam, purposely applied, as explained; 2, immersing the calcined mineral in water, or otherwise wetting it with water, and subsequently driving off the surplus moisture, or that which has not chemically combined with it, by means of heat purposely applied, and over and above that which is generated by the action of the water on the material, as described. *Patent completed.*

1074. S. S. MARLING. *Improved machine for scouring, washing, and cleansing woollen cloths and other fabrics.* Dated April 28, 1863.

This invention is not described apart from the drawings. *Patent completed.*

1075. J. ROWLEY. *Improvements in the means or apparatus employed for recovering the fibres of wool from fabrics or materials composed of wool combined with cotton and other vegetable substances.* Dated April 29, 1863.

In carrying out this invention, the patentee first cleanses and then thoroughly saturates the woollen rags, fabrics, or other materials to be treated by steeping them in dilute acid (by preference, sulphuric), the strength being varied according to the nature of the materials to be operated upon. The rags or materials, after having had the steeping liquor discharged therefrom in any convenient manner, are placed (by preference for the purpose of being dried) in a rotating drum or cylinder made of wire gauze, or perforated metal or material, and a current of hot air is forced or drawn through them from a tube or flue suitably constructed for this purpose, by which means the rags or other materials are dried. The rags or materials having been thus dried, are deposited in boxes or trucks, and as they are deposited therein they are, by preference, intimately combined with, and embedded in, heated sand, previously prepared and cleansed from all oxidizable metallic substances at the same time. The boxes or trucks are then, by preference, raised to the upper storey of the building in which the operation is carried on, and after remaining in the hot sand or other material for a suitable length of time, according to the nature of the fibrous materials under operation, they are discharged, and the sand is separated therefrom by rotating sieves, or by other convenient mechanical means. The cotton or other vegetable substances contained in the fabrics or materials, after being treated as above described, will be so far destroyed as to be readily separated from the fibres of the wool previously combined therewith, the latter being unaffected by the process employed. *Patent completed.*

1076. E. ROWLAND. *Certain improvements in apparatus for weighing solid bodies and for measuring fluids, part of which improvements are applicable to the opening and closing of "dampers."* Dated April 29, 1863.

This invention relates to an apparatus for weighing solid bodies or measuring fluids wherein water or other fluid confined within a chamber is applied and employed as the counterbalance to the body to be weighed, such communicating chamber with a graduated tube to indicate the weight by the height of the water in the tube. A second part of the invention relates to a similar arrangement of apparatus to be employed to open and close dampers in the flues of a furnace employed to heat a steam boiler or generator; the rise and fall of the beam being effected through the medium of the water (instead of being adapted to weighing) is applied to the aforesaid purpose. *Patent abandoned.*

1077. W. and E. TARR. *An improvement in pianofortes.* Dated April 29, 1863.

This invention is not described apart from the drawings. *Pvtent completed.*

1078. W. E. GEDGE. *An improved system of permanent advertisement.* (A communication.) Dated April 29, 1863.

We cannot here give space to the details of this invention. *Patent abandoned.*

1079. E. and F. A. LEIGH. *Improvements in cotton gins, and in the method of driving the same, part of which improvements is applicable to other purposes.* Dated April 29, 1863.

In that kind of gin called the Macarthy gin, the patentees place the doctor in a horizontal position, and cause it to press on the top of the roller instead of pressing against the side, as heretofore employed, the beater acting horizontally instead of vertically. This position admits of a vertical feed more conveniently (whether fed by hand or power), and causes the roller to bite or nip the cotton with greater certainty. They make the rollers in the ordinary manner, but place under the leather some elastic substance. The beater can either be actuated by a crank motion, or fixed upon springs; in the latter case, they cause a notched wheel to be fixed ou each end of the roller. These notched wheels or wipers have as many teeth as the number of strokes required of the beater for one of the roller—commonly five or six—so that when motion is given to the roller the notches, acting against steel pins or bowls fixed to the beater or to the springs, press it back, and allow the stroke to be made by the force or elasticity of the springs. This arrangement dispenses with the crank shaft. The next improvement is the application of a maintaining power for gins, and other machines turned by hand. This they accomplish by a small fly-wheel keyed on a light steel shaft, and accurately balanced. This shaft runs upon friction bowls having small steel gudgeons, and is turned by a strap from the gin roller or otherwise, so that it can be used or not at pleasure. In feeding the gin, they place a grid in a vertical position over the gin roller through which the seeds are pushed by the action of the beater. These gins may be made with one, two, four, or more rollers. *Patent completed.*

1080. W. RODGER. *Improvements in anchors.* Dated April 29, 1863.

This invention relates to those parts which are usually termed the crown, the arms, and the palms, and the object in view is to obtain a greater amount of strength and holding power with a given weight of iron. The additional strength is obtained by partly making the arms shorter than usual in proportion to the length of the shank—that is to say, about one-fourth part, instead of about one-third, and partly by their sectional form. The sectional form of the shank is rectangular at its junction with the arms, and square at the shank close to the collar for the stock. But the sectional form of the arms is widely different from that of any other anchor now in use, being of a wedge form, varying in sharpness from the throat to the head of the palms. The back part of the arms is made parallel from palm to palm, and is much thicker than their front part, which is tapered in the direction of the point; and the arms from the crown to the head of the palms being much broader in the direction of the strain than is usual, gives them a great increase of strength. *Patent completed.*

1081. H. WORMS. *Improvements in apparatus for elevating guns.* Dated April 29, 1863.

For the purposes of this invention, apparatus is applied at the hinder part of the gun carriage in the following manner:—Two toothed sector racks are used, which slide in guides below the rear end of the gun at their upper ends; these two sector racks are connected together by a bar or axis on which it is preferred to place a roller for the hinder part of the gun to rest upon. Motion is communicated to the two toothed racks by means of two toothed wheels on an axis turning in bearings carried by the two sides of the gun carriage. The axis and toothed wheels receive motion from another or driving axis or axes, on which there are two toothed pinions which take into and drive the toothed wheels on the first-mentioned axis. On the outer ends of the driving axis or axes are cranked handles, by which motion is communicated thereto. In order that the elevation of the gun may at all times be known, there are graduated ratchet discs or plates on the driving axis or axes, and a stop or catch to take into such teeth, and thus to retain the driving axis or axes from turning after being set, and such teeth are at regulated distances apart, so as to indicate (in degrees or parts of degrees) the elevation of the gun. *Patent completed.*

1082. M. BARLAND and E. H. C. MONCKTON. *Improvements in apparatus for withdrawing milk from cows and other mammiferæ, and for conducting it when withdrawn to appropriate receivers.* Dated April 29, 1863.

This invention consists in constructing a small tube or pipe of metal, electro-plated or otherwise, ivory, vulcanite,

ebonite, or other suitable substance, the diameter being about 3-16ths of an inch, more or less, and the length about 1½ to 3 in., more or less, one end being tapered to a conical or blunt point or head, and being perforated with several holes of an oval, round, or other shape. One of these tubes is to be inserted in each teat of the animal; and in some cases it may be necessary to keep the tube in position in the teat by means of an elastic band encircling the teat, and pressing it against the surface of the tube. So also the tubes may be secured against the danger of penetrating too deeply into the teat by means of a disc or small head plate fixed around the tubes near their lower ends. The effect of the insertion of these tubes will be that the milk will flow through the perforations into the tapered ends of the tubes, and, consequently, will pour through them in a regular and continuous stream until the milk is exhausted. The invention also consists in the employment of suitably constructed receivers for the reception of the milk, such receivers being somewhat of the form of the udder of the cow, and attached to the cow by straps or otherwise. *Patent completed.*

1083. F. GRETTON. *Improvements in heating the contents of mash tuns.* Dated April 29, 1863.

This invention consists in the combined employment of coils of pipes or heating cases, both at the lower part or bottom of the tun, and at or near the top surface of the wort or liquor contained in the tun, the surface pipes or heating cases being made to float by being connected to buoys or air-vessels. The inventor fits flexible pipes to the surface heaters to enable them to rise and fall with the contents of the tun, and he passes steam, hot water, or hot air through the pipes and heating cases. The invention also consists in heating the contents of mash tuns by means of pipes or cases made to float at or about the surface thereof, and supplied with steam, hot water, or hot air. *Patent abandoned.*

1084. G. HOLCROFT. *Improvements in the construction of pyrometers.* Dated April 29, 1863.

This invention consists in constructing pyrometers with a column of mercury acted upon by well-adjusted currents of heated air. *Patent abandoned.*

1085. H. W. RIPLEY. *Improvements in apparatus for printing fibrous materials.* (A communication.) Dated April 29, 1863.

This invention is more particularly applicable to the printing of fibrous materials which are afterwards to be drawn and spun into yarns, though fibrous substances may in like manner be printed after they have been spun, and these improvements may be used separately or in combination with suitable mechanism for drawing the fibrous materials before they are caused to be spun. The printing liquid is applied to a roller, the circumference of which is covered or coated with a porous cloth or material; the printing liquid is applied in such manner as to prevent there being any excess of colour upon the surface of the roller, or the excess of printing liquid may be expressed or removed from the outer surface of the soft and porous covering of the roller, in order that fibrous materials when they come in contact with the roller in the process of printing may not by the simple contact have colour transferred to them from the roller. For this purpose the inventor has in some cases used thick woollen cloth to cover the roller, and in other machines the roller has been covered with india rubber cloth, and over it thin woollen cloth. Both these modes of covering the roller have answered the purpose, but other elastic porous coverings may be employed. The colour is conveniently applied to the covered roller, by means of another roller partly immersed in the printing liquid, and revolving in contact with the covered roller so as to apply printing liquid thereto, and any excess of printing liquid is expressed either by a third roller or otherwise from the soft and porous coating of the covered roller. The printing is effected by means of a printing roller or surface on which the desired device is raised or engraved. This printing surface is employed to press the fibrous material against the covered roller, and the raised parts of the pattern press the fibrous materials into the soft and porous covering of the roller in which the colouring liquid is contained, and the fibrous material then receives colour from the roller. *Patent completed.*

1086. M. HENRY. *Improvements in apparatus for manufacturing beton and artificial stone, pugging clay, &c.* (A communication.) Dated April 29, 1863.

This invention mainly refers to the manufacture and application of a certain beton, composition, or artificial stone, for which François Coignet obtained British letters patent, respectively numbered 2,659 and 2,757, and dated 26th November, 1855, and 6th December, 1859. The invention first relates to improved machinery for manufacturing Coignet's patent beton or artificial stone, such machinery being also applicable for mixing concrete, pugging clay, working mortar, and other similar purposes. Machines hitherto constructed for these objects have been provided with one or two small ejection orifices, through which the materials were forced out or discharged. Now, according to this invention, the machine is formed with an ejection opening extending continuously, or nearly continuously, or without, or nearly without, division or break round the discharge end of the machine. Or large or numerous, or both large and numerous, ejection openings are distributed all round that end of the machine. By these means the materials, after having been mixed, pugged, or treated in the machine, are discharged therefrom freely and continuously with little or no obstruction or resistance. The chamber or casing of the machine is constructed of three parts—in one of which the ejection openings are below the two others, and one of these latter is removeable, so that the chamber may be easily cleansed. In this chamber a shaft revolves, carrying appliances for mixing, kneading, or otherwise acting on the materials, and others for pressing, drawing, or heaping them towards the ejection orifices, and for discharging them therefrom. The passage through the ejection orifices may be regulated by an annular valve. *Patent completed.*

PROVISIONAL PROTECTIONS.

Dated October 9, 1863.

2480. D. Lange, 5, Trinity-square, Tower-hill. Certain improvements in railway wrappers.

Dated October 20, 1863.

2568. M. Petenkofer, professor of chemistry, Bavaria. Restoring the surface of pictures in oil without any danger to their original state.

Dated October 22, 1863.

2599. F. Bullock, rear-admiral, 16, Richmond-terrace, Gravesend. Improvements in ships' logs or apparatus for ascertaining the speed of ships.

Dated October 31, 1863.

2702. W. Law, Northampton, cabinet manufacturer. Improvements in the construction of articles of furniture known as wardrobes, including improved arrangements for attaching doors to the same, such improvements in attaching doors being applicable to other articles of furniture.

2708. E. Jones, Charlton. Improvements in the manufacture of bricks, drain pipes, traps, sewage tanks, and water-closet pans and valves, and the machinery and apparatus necessary for the same.

Dated November 3, 1863.

2715. D. Davy, jun., Sheffield, engineer. Improvements in steam hammers.

Dated November 4, 1863.

2733. W. Audinwood, Castle Donington, Leicestershire. Improvements in thrashing machines.

Dated November 5, 1863.

2735. G., W., and J. Craven, Vauxhall Iron Works, Manchester, engineers and tool makers. Improvements in machinery for cutting and planing iron and other metals, particularly applicable to machinery for cutting and planing armour plates.

2740. B. Blackburn, Chelsea, esquire. An improved coupling or buckle.

Dated November 6, 1863.

2752. R. Sellar, Huntley, Aberdeenshire, agricultural implement manufacturer. An improvement in the construction of harrows.

2760. W. D. Allen, Laithfield-house, Norfolk-road, Sheffield, steel manufacturer. Improvements in casting ingots of steel.

2764. W. E. Newton, 66, Chancery-lane, civil engineer. Improvements in sewing machines. (A communication.)

Dated November 7, 1863.

2770. J., J., and G. W. Dyson, Tinsley, Yorkshire, ironfounders. Improvements in the method of, and machinery for, forming metal plates, bars, and rods taper.

2776. C. D. Abel, 20, Southampton-buildings. Improvements in apparatus for raising and lowering bodies. (A communication.)

Dated November 11, 1863.

2798. F. Testuz, 11, Air-street, Piccadilly. Improvements in breaks applicable to railway and other carriages.

2800. W. R. Bowditch, St. Andrew's, Wakefield, clerk. Improvements in apparatus used in gas-lighting.

Dated November 12, 1863.

2811. H. J. Simlick, Old Ford-road, Bow. Improvements in the manufacture of fusees or matches employed to light cigars and pipes.

2813. B. Peake, Coventry, ribbon manufacturer. Improvements in the manufacture of neck ties, cravats, and waistbands, which improvements are also applicable to other articles of wearing apparel.

2815. A. Illingworth, Bradford, Yorkshire, spinner. Improvements in means or apparatus employed in preparing and twisting cotton wool and other fibrous materials.

2817. G. Davies, 1, Serle-street, Lincoln's-inn. Improvements in springs for railroad cars and other similar purposes. (A communication.)

2821. G. H. Brockbank, Great College-street. Improvements in pianofortes.

2823. W. E. Newton, 66, Chancery-lane, civil engineer. Improvements in gas burners. (A communication.)

2825. D. M. Fyfe, Maidenhead, adjutant of the 19th Regiment of Berks Volunteers. Improvements in carriages and apparatus for raising, removing, and transporting heavy bodies from place to place.

Dated November 13, 1863.

2827. B. Marriott, 38, Upper-street, Islington, and C. Radcliff, 201, Hampstead-road. Improvements in dead beat independent centre seconds watches.

2829. W. Chambers, Whitefield, near Manchester, bleacher. Improvements in machinery for beetling and finishing cloth.

2831. H. F. Hodson, 179, Western-road, Brighton, agricultural agent. Certain improvements in cigars.

2833. E. Spencer, Oldham, machinist, and J. Dodd, machinist. Improvements in mules for spinning and doubling.

2837. T. Harrison, Tudhoe, near Ferry-hill, Durham, mechanical engineer. Improvements in machinery for cutting and excavating coal and other minerals, applicable also to other mining purposes.

Dated November 14, 1863.

2841. De B. Hughes, Liverpool, scenic artist. Improvements in producing dramatic and other like effects on the stage or in a room.

2843. J. Ellison, Leeds. Improvements in flour dressing machines, termed "silk reels."

2847. A. Ellissen, City of London, merchant. Improvements in preventing the fouling of the bottoms and sides of ships and vessels, particularly applicable to ships and vessels constructed of, or sheathed with, iron.

2849. G. Barker, 59, Broad-street, Pendleton, merchant. Improvements in the construction of syphons for taking off liquid sewerage, overflow of rivers, and other like purposes.

2851. G. H. Courtney, Broadway, Stratford, Essex. Improvements in tills or receptacles for money.

2853. G. Lindemann, Salford, engineer. Improvements in machinery or apparatus for singeing woven fabrics.

2855. L. Mackirdy, Greenock, sugar refiner. Improvements in saturating, washing, and cleansing charcoal and other matters, applicable also to the separation of syrups from sugar.

2859. J. Southgate, 75 and 76, Watling-street. Improvements in overland and other portmanteaus.

2861. J. Walmesley, Berlin, Canada, farmer and waggon maker. Improvements in machinery for pulverizing and cleaning the soil, and scattering seed, guano, bone dust, and other substances thereon.

Dated November 16, 1863.

2863. E. and F. A. Leigh, Manchester, mechanical engineers. Improvements in the method of driving and feeding cotton gins and of conveying away the ginned cotton and seeds therefrom.

2865. S. Cameron, plumber, and W. Johnston, metal merchant, Glasgow. Improvements in taps or valves in pipe joints, and in the valvular mechanism of water-closets

2871. I. Pomès, Condon, France, gentleman. An improved hydraulic motor.

2875. R. A. Brooman, 166, Fleet-street, patent agent Improvements in the manufacture of salt, and in boilers to be fed by salt water. (A communication.)

Dated November 17, 1863.

2877. F. W. Burton, 20, Somerset-place, New North-road, ornamental carver. Improvements in the construction of music stools, tables, and other articles of furniture, and in means of securing such articles to floors.

2879. V. Baker, lieut.-colonel of Her Majesty's 10th Regiment of Hussars, Dublin. Improvements in breech-loading ordnance, and in apparatus connected therewith.

Dated November 18, 1863.

2881. W. Pratchitt, J. Blaylock, and J. Pratchitt, Carlisle, machinists. Improvements in, and applicable to, moveable platforms for railway stations.

2885. R. W. Siever, Guildford-street, Russell-square. Improvements in jacquard machines. (A communication.)

2887. J. R. Cooper, Birmingham, gun manufacturer. Improvements in the manufacture of barrels for firearms, and in machinery to be used in the said manufacture.

2889. J. Elder, Glasgow, engineer. Improvements relating to floating and other docks.

2891. J. Mackew, Leicester, machinist. Improvements in machinery for making looped fabrics.

2893. J. G. Jennings, Palace-road, Lambeth, sanitary engineer, and M. L. J. Lavater, Bath-street, Newgate-street, india rubber manufacturer. Improvements in the manufacture of tubes, rings, and cords of india rubber, and in covering telegraph wires.

2895. P. St. G. Groome, 9, Waterloo-place, Pall Mall, captain R.A. Improvements in ships or vessels for war and other purposes.

PATENTS APPLIED FOR WITH COMPLETE SPECIFICATIONS.

Dated November 18, 1863.

2884. J. H. Johnson, 47, Lincoln's-inn-fields, gentleman. Improvements in rotary engines. (A communication.)

Dated November 20, 1863.

2926. H. A. Bonneville, 38, Porchester-terrace, Bayswater. Improvements in preserving grain, flour, and other substances, and in the apparatus connected therewith. (A communication.)

Dated November 21, 1863.

2941. J. Steart, 5, St. James-road, Bermondsey, manufacturer. Extracting the fibre from zostera marina and other aquatic vegetable productions.

Dated November 24, 1863.

2950. St. G. Gregg, 3, Austin-friars, and T. Gray, Mitcham, bleacher. The production of thread, cordage, and woven textile fabrics from prepared fibre of hemp, or any of the plants known of the order or genus "Canabis," and in mixing such prepared fibre with cotton, silk, or animal wool.

Note.—Specifications will be forwarded by post from the Great Seal Patent Office (publishing department) on receipt of the amount of price and postage. Sums exceeding 5s. must be remitted by Post Office Order, made payable at the Post Office, High Holborn, to Mr. Bennet Woodcroft, Great Seal Patent Office, 25, Southampton-buildings, Chancery-lane.

LIST OF DESIGNS FOR ARTICLES OF UTILITY REGISTERED.

Dates of Registration.	Nos. in Register.	Names and Addresses.	Subjects of Design.
May 6,	4555	J. Gunner, Enfield	Ramrod.
,, 7,	4556	H. Twelvetrees, Bromley	Mangle.
,, 8,	4557	G. Hazelton, Birmingham	Locket-case.
,, 13,	4558	W. Blott, New Oxford-street	Photogrphc.printing frame.
,, 20,	4559	H. Hanly, Regent's-park Barracks	Incubator.
,, 26,	4560	R. Rains, Blackfriars	Machine for freezing.
,, 30,	4561	S. T. Bateson, Bolton-street, W.	Pipe.
June 1,	4562	W. Tonks and Son, Birmingham	Pulley.
,, 1,	4563	F. Hall, Worcester	Meat safe.
,, 2,	4564	G. Lloyd, Birmingham	Insect trap.
,, 2,	4565	W. Tonks and Son, Birmingham	Call bell.
,, 4,	4566	A. L. Salomons, St. Paul's-churchyard	Waistbelt.
,, 9,	4567	M. L. Jacob and L. Woolf, Birmingham	Slide for scarfs.
,, 20,	4568	W. H. Tuffrey, Cornwall	Plough.
,, 26,	4569	G. Wright and Co., Rotherham	Kitchener.
July 3,	4570	F. Barker, Hammersmith	Packets of paper.
,, 18,	4571	T. T. Topling, Sunderland	Fire-bars.
,, 18,	4572	H. Bell, Birmingham	Hob-nail.
,, 20,	4573	H. Gillott, Birmingham	Easel.
,, 29,	4574	B. Miller, Leeds	Steamengine standard.
Aug. 6,	4575	W. Oxley, Manchester	Steam trap.
,, 7,	4576	W. B. Lord, Sandgate	Cartridge case.
Sep. 14,	4577	C. Smith, Union-st., E.C.	Child's normal.
,, 14,	4578	G. P. Hill, Wood-st., E.C.	Button gauge.
,, 18,	4579	H. Gaball, Burlington-gardens	Chest protector.
,, 24,	4580	J. L. Thomas and Co., Exeter	Lamps.
,, 28,	4581	J. Kenney, Birkenhead.	Water Tue-iron.
,, 30,	4582	H. J. & D. Nicoll, Regent-street	Wing cape.
Oct. 6,	4583	J. Parkes, Handsworth.	Handle.
,, 6,	4584	C. Rowley & Co., Brmghm	Buckle.
,, 9,	4585	T. P. Hawkin, Brmghm.	Hooks.
,, 15,	4586	R. Howson and E. F. Jones, Middlesboro'	Blast cylinder.
,, 17,	4587	J. F. M. Hawkins, Nrthall	Feeding trough.
,, 19,	4588	J. E. Maddox, University-street	Bed bath.
,, 24,	4589	P. Hughes, Paddington	Counter box.
Nov. 2,	4590	W. N. Nicholson, Newark	Wine bin.
,, 4,	4591	W. J. Gilbert and Co., Birmingham	Box iron.
,, 6,	4592	H. J. Cave, Edward-st. W	Portmanteau.
,, 7,	4593	S. and T. Carrington, Stockport	Ventilating.
,, 9,	4594	H. Elliott, Birmingham	Firearms.
,, 9,	4595	Mechi & Basin, Regent-street	Dressing bag.
,, 13,	4596	T. R. Withecombe, Manchester	Tobacco pipe.
,, 21,	4597	W. Brown, Glasgow.	Sofa bench.
,, 21,	4598	T. Atkins, Birmingham	Fastener for tables
,, 27,	4599	T. Evans, Pentonville-rd.	Dome of parasol.
		PROVISIONAL REGISTRATIONS.	
May 1,	1442	W. Oliver, Bath-street	Watch protector.
,, 11,	1443	J. Harper, Powick	Cravat.
,, 18,	1444	Carthian and Corbiere, Cannon-street	Buffet de Garcon.
,, 21,	1445	R. A. Margetson, Norwich	Flyer and handle.
,, 28,	1446	H. Heyes, Chichester-rents, E C.	Copying press.
,, 29,	1447	T. Thomas, Regent-street	Landing stage.
June 2,	1448	C. Blackman, Regent's-park Barracks	Crib-biting preventor.
,, 9,	1449	T. Hickin, Birmingham	Syringe end.
,, 9,	1450	W. Lee and Co., Cannon-row, S.W.	Machine for ginning cotton.
,, 17,	1451	J. Marples, Sheffield	Setting saws.
,, 24,	1452	J. Norcott, Mrylebone-rd	Carriages.
,, 24,	1453	T. H. Webster, Dublin	Spring boot.
,, 26,	1454	G. Benton and J. Stone, Birmingham	Water spreader.
,, 30,	1455	W. Baddeley, Islington.	Valve strainer.
July 4,	1456	C. Young, Edinburgh	Curling Rink.
,, 9,	1457	W. Riddle, Sth. Lambeth	Candlestick.
,, 13,	1458	S. B. Solomons, Albemarle-street	Spectacles.
,, 16,	1459	F. J. Campbell, Lower Thames-street	Boxes for wine.
,, 29,	1460	J. G. Winton, Southwark	Cistern.
,, 31,	1461	T. Spenceley, Wandsworth-common	Fastener for scarfs.
Aug. 1,	1462	T. Simmons, Birmnghm.	Watering can.
,, 8,	1463	T. Bissell, Tooley-street	Heel pad.
,, 12,	1464	H. Gaball, Burlington-gardens	Spine protector.
,, 14,	1465	J. G. Winton, Gladstone-street	Gland for tubes of surface condensers.
,, 15,	1466	T. Simmons, Birmnghm.	Fumigator.

THE MECHANICS' MAGAZINE.

Contents of the Last Number:—

THE
MECHANICS' MAGAZINE.

LONDON, FRIDAY, DECEMBER 11, 1863.

THE CATTLE SHOW.

UNDOUBTEDLY the event of the week has been the Smithfield Club Cattle Show, and this not only as regards London, but, to a great extent, the country at large as well. Periodical exhibitions of stock and implements, affect the interests of both the farmer and the agricultural engineer very considerably, forming as they do constantly recurring records of progress and stimuli to renewed exertion, which have been up to the present highly conducive to the welfare of the community who make mother earth serve them directly with the comforts, as well as the necessaries of daily life. With the recollection of the Worcester Show fresh in the mind, the visitor to the Agricultural Hall, at Islington, may not have found much that was new, but he will surely have fonnd a great deal that was good, albeit devoid of the peculiar charm which is said to hang round novelties. It is probable that country gentlemen have recognized many an old face (we were about to say old friend) within the precints of the cattle pens; and we, who confess to feeling little interest in that department, have certainly met with many an old friend in the shape of mechanical contrivances and arrangements, among the implements. "There is nothing new under the sun," said a wise man of old; and it would seem that the proverb is especially applicable to the works of the agricultural engineers just now. As a class, they seem inclined to rest from the labour of originating new things, for the present preferring to go on improving on existing devices, rather than plunge into the cold bath of invention. Perhaps, it is better so; the creation, so to speak, of a new implement, which shall possess sufficient good in itself to enchant a discriminating public, being anything but an easy task. After all, your thorough English farmer is not very easy to please, and is usually captious and critical enough to render the path of the inventor whotries to supply his wants, real or imaginary, sufficiently thorny and rugged, to make the expediency of entering on it at all, a thing to be thought about two or three times. Nevertheless, there are prizes to be drawn in agricultural engineering, as well as in any other pursuit; and when once a plough or a thrashing machine, a steam engine or a cultivator, has borne the test of experience, it is certain that want of appreciation will not cause a slack sale. Notwithstanding a little crustiness now and then, the English country gentleman is a pleasant fellow to work for; and he and the engineer have got on very well togetherso far; and we see no danger of the harmony being interrupted.

The Agricultural Hall, at Islington, appears to us to be, in every respect, thoroughly well adapted to the purpose in view. Our readers are probably aware that its erection, or at least completion, is comparatively recent. The Smithfield Club Show, of 1862, in December, being the first Exhibition held within its walls. It consists of a very well proportioned hall, covered in by a handsome iron roof of considerable span, and surrounded by wide galleries supported on cast-iron pillars, to which easy access is attained by numerous staircases. These galleries are devoted, just now, to the smaller implements—such as chaff-cutters, root-pulpers, light reaping machines, and samples of cereals, roots, and artificial manures. For all these things there is ample room—a circumstance highly conducive to the comfort of both visitors and exhibitors. Would that we could say as much of the ventilation. The centre of the large area below is divided by iron rods, into compartments devoted to sheep and horned cattle; while the space under the galleries is pretty well filled up by the heavier class of agricultural machinery. Here, again, there is a total absence of crowding; most of the exhibitors having had the good taste to avoid a mere display of a multitude of implements, of the merits of which no one, however privileged, could by any possibility judge without great exertion and some personal risk. The means of obtaining access to the Hall were on the whole good, though by no means incapable of improvement. On Monday especially, the crowding at the exhibitors' and ticket entrance was very unpleasant, and called forth many animadversions on the arrangements.

Anything like a detailed description of the implements exhibited, would at once exceed our space, and prove uninteresting. Literally speaking, the visitor might walk through the building east and west, north and south, without discovering anything very new. Perhaps the most remarkable feature of the Exhibition lies in the self-propelling engines. In the International Exhibition of 1851 there was not one traction engine; and it is not perhaps saying too much, to state that a general belief existed that none could be contrived to answer any commercial purpose. All that is changed now; and, both in England and in the colonies, road locomotives, day by day, act a more prominent part. Our readers will doubtless recollect what an important class they formed at Kensington last year, and some progress has been made since. Makers of this description of steam machinery daily become more enterprising, and the dimensions of three or four of those shown at Islington, would have put the railway locomotives of twenty years ago to the blush. Messrs. Aveling and Porter, Garrett, Clayton and Shuttleworth, Fowler, and Howard are exhibitors in this class. The workmanship of their engines is generally speaking good, although individual arrangements are not yet all that they should be. In the first rank we must place an 8-horse engine, by Messrs. Aveling and Porter, which appears to us to meet almost every possible requirement in the most efficient manner. Perhaps there is not at present a firm in existence which has had so much practical experience in the road locomotive. Although their engines are, comparatively speaking, a thing of yesterday, Messrs. Aveling and Porter have completed altogether ninety-seven engines of the kind, ninety-six of which are in use. The engine exhibited is of 8-horsepower, according to the method of calculation adopted by the Royal Agricultural Society, having a 9-in. cylinder by 12 in. stroke. The gross weight full, is about 9·5 tons. The general arrangements are too well understood to need description; and the only novelties embraced in the present engine are a simple modification for obtaining two speeds, and an improved method of taking up the slack of the chain. Close behind the fly-wheel shaft a second is placed, carrying two spur wheels of different diameters, which are put in motion by pinions on the fly-wheel shaft. Either of these wheels can be placed in gear by simple means, according as the fast or slow speed is required; the other, of course, being thrown out for the time being. This spur-wheel shaft is supported in brasses, which can be moved up and down as occasion requires in curved brackets bolted to the boiler. These brasses rest on iron packing pieces of various thicknesses. When the chain becomes too slack by wear, it is only necessary to raise the shaft and brasses in the curved plummer blocks, and replace a thin packing piece by one a little thicker, to take up the slack of the chain. The whole arrangement is kept tight by suitable set screws, and answers its purpose in the most efficient manner; it being impossible, with the most moderate amount of care, to put the second shaft out of parallelism with the first. The chain is made with solid block links 2 in. wide, each finished in the shaping machine. Thus, a large bearing surface is provided, and wear is reduced to a minimum. It may not be out of place to state that one of these engines, of a somewhat larger size, has travelled over 5,000 miles of country roads, and is still a very efficient machine, having on one occasion drawn 26·5 tons, in addition to its own weight, up an incline of 1 in 12, 502 yards long, a performance almost unique.

Messrs. Garrett and Son show a very neat single cylinder 8-horse self-propeller, embodying Mr. Aveling's patents. The cylinder is placed in the smoke-box just beneath the chimney. This engine is without the double speed gearing. The driving wheels are 3 ft. 6 in. high, and very wide on the face. It is the only road locomotive in the Exhibition provided with springs, if india-rubber blocks, fitted in a very simple and ingenious axle-box deserve the name. It is strange that engineers should willfully shut their eyes to the advantages to be derived from the interposition of a flexible medium between the dead weight and the carrying wheels. It is in vain to urge that, at slow speeds, expedients of the kind are unnecessary. We never could understand why speed should be kept down to the same rate with an unloaded as with a loaded engine. One of the best traction engines we ever met with, could draw 30 tons comfortably on a good road at 2½ miles per hour, and run light, at from 7 to 8 miles with the greatest ease, thanks to the long easy springs so universally eschewed. That they form an item of expense at first, we admit; but the saving which they effect in the subsequent outlay for repairs far exceeds their first cost. Messrs. Garrett also show a well-arranged double cylinder portable 12-horse engine; a 13-row corn drill; a very good finishing thrashing machine, with a single fan on the drum shaft; and several other articles, the workmanship of which is quite good enough to maintain the well-earned reputation of the firm.

Clayton and Shuttleworth exhibit a traction engine, intended for Egypt; the cylinders, 8·5 in. diameter, by 14 in. stroke, are placed in the smoke-box just beneath the chimney; the driving wheels, nearly 7 ft. high, have cast-iron cellular rims and wrought-iron spokes. The general arrangements of the machine are very good, and the workmanship excellent. The driving gear is so very peculiar, that, without drawings, it would be impossible to give an accurate idea of it. Suffice it is to say, that the driving wheels each revolve loose on the main axle, which is immoveable. Just in the rear of the boiler, and at a convenient height above the fire-door, runs a transverse shaft, carrying a differential system of gearing at the ends. This shaft is driven by a pitch chain from the crank axle. Inside each driving wheel is bolted a large spur wheel, put in motion by the transverse shaft and differential wheels. The whole affair looks complicated, but is really very simple. The effect produced is, that so long as the resistance is the same to both drivers, they will

both be propelled with equal velocity. If, however, the engine is in the act of turning a corner, the inside wheel will simply remain at rest, or nearly so, because the action of the steering gear places an obstacle in the way of its progress; the outside wheel will then advance at a speed as much greater than its normal velocity, as that of the inside wheel is less. Thus, if one wheel were blocked, the other wheel would proceed at a double velocity, the engine shaft still making only the same number of revolutions; and this action is so perfect, that the steering is effected with the greatest possible ease. The whole arrangement is extremely ingenious, and being well carried out with cast-steel pinions, &c., should prove very durable. The steering is effected by an endless screw and pitch chain; the principle involved being none of the best, inasmuch as the screw offers a nearly rigid *point d'appui* to any force impressed on either fore wheel by obstructions on the road, and the chances of striping the teeth of the worm wheel are materially increased, in consequence. While speaking of the fore carriage and its connections, we may remark that no universal joint arrangement is provided to permit either end of the axle to rise or fall independently of the engine. This may seem trifling; but it is on such trifles that the success of the road locomotive depends. It is folly to attempt to compel an engine to proceed over irregular ground on four rigid points of support. A swivel joint in front obviates the difficulty by reducing their number to three; the entire machine is spared many a strain thereby, and the operation of steering is greatly facilitated. Messrs. Clayton and Shuttleworth also exhibit a double cylinder stationary engine, fitted with expansion gear; a thrashing machine; portable engines, &c., of excellent workmanship and good design.

Messrs. John Fowler and Co.'s stand presents little with which the public are not perfectly familiar, save a rather coarsely-got-up traction engine, intended to carry an underneath clip drum. The driving gear is completely boxed up within a heavy plate-iron inclined trunk, carrying the outside bearings of the shafts, so that it is not very easy to determine what it is like. The steering gear is in one sense extremely neat and compact, yet as unmechanical and defective in principle as it well can be. A large hand wheel on the foot plate, far removed from any bearing, puts an endless screw in motion, through the medium of some gearing and an inclined shaft about 18 ft. long. The endless screw takes into a very small, quadrantal, toothed arc on the fore carriage. This certainly does not look like good engineering. The foot plate of a traction engine is generally far too small to render it advisable that the steersman should discharge his duties there. So long as a locomotive is intended merely for ploughing, the arrangement may be tolerated, because the engine-driver can guide the engine forward for the few yards required at a time. The machine in question, is, however, set forth as a traction engine to which the winding drum *may* be attached, if deemed desirable; and such being the case, the steering wheel has no business on the foot plate. An engine and windlass, similar to that shown last year at Kensington; a set of ploughs, cultivators, &c., are highly creditable to the makers, and appeared to meet with thorough appreciation from the public.

Messrs. Howard exhibit a set of their patent steam-cultivating apparatus, including, of course, the inevitable 10-horse self-pro... by Clayton and Shuttleworth, and very similar in every respect, save the absence of differential gear, to the one shown by that firm and already described. The workmanship of all these articles is above the average. The merits of the system are too well known to require comment.

Messrs. Hornsby and Son exhibit a very highly finished double cylinder portable 10-horse engine, suitable for ploughing or other purposes. The cylinders are placed in a steam chest over the fire-box. The propriety of using longitudinal wrought-iron stay rods from the cylinder covers to the crank-shaft brackets, is more than doubtful. The boiler must expand far more than they can, removed as they are from any direct source of heat; hence, a tremendous strain must be exerted on the cast-iron brackets, which appear to be quite strong enough in themselves to support any legitimate strain to which they may be exposed, without the aid of such questionable expedients. We noticed a very ingenious and carefully got up reaping machine, in the same stand, which delivers the corn from an inclined table, by means of a patented arrangement of endless chains, provided with fingers, which sweep off the cut corn and place it by the side of the machine. Messrs. Hornsby also exhibit an excellent thrashing machine, ploughs, and many other articles.

Messrs. Tuxford and Son show a 10-horse power patent "housed" engine, got up as usual with great care, an Appold centrifugal pump, saw-bench, &c., which call for no particular remark.

Messrs. Barrowes and Carmichael exhibit an 8-horse portable engine, one of the best of its kind, as far as neatness, simplicity, and good workmanship are concerned, that we have ever seen. The cylinder can be removed from the boiler with the greatest ease; all the bolts being accessible without removing the lagging. The crank is slotted out from the slab. The cross-head is peculiarly elegant in its construction. The position of the cylinder on the centre of the fire-box shell is objectionable, however, as it entails a very high crank-shaft. The engine is provided with steel volute carrying-springs — an arrangement which we trust will soon become more general.

Mr. F. H. Wenham exhibits the most remarkable engine within the walls of the Agricultural Hall. This little machine, weighing barely 2¼ tons, and scarcely larger than an ordinary 2½-horse portable, has indicated full 16-horse power. It is provided with a high and low pressure cylinder, placed one at each side of the chimney, on the haunches of the smoke-box. The smaller of the two is 5 in. in diameter, the larger 8¼ in.; the stroke of both being the same, 12 in. The cranks are placed at an angle of 90 deg.; steam is led direct from the boiler to the small cylinder, the exhaust steam from which is conveyed to a superheater in the smoke-box, the tubes of which are coincident with the boiler flues, so that both may be swept out at one operation. The steam dried and increased in volume, by a temporary sojourn here, is then led into the large cylinder, from which it finally escapes into the chimney. All the arrangements are simple and scientific, and we can very well credit the statement of the patentee, that he has obtained 16-horse power with about 32lbs. of coal per hour. Indeed, indicator diagrams, with which we have been favoured, leave no room for doubt as to the actual powers of a machine, which well deserves the favour of all employing portable engines. The small weight for a given power is in itself no slight advantage in a hilly or difficult country.

Mr. Collinson Hall exhibits a model of his ploughing apparatus; some illustrative drawings; and a steel link rope, constructed on his principle, which has ploughed over 600 acres of stiff land and looks none the worse. Mr. Hall eschews the wire rope, preferring one made of steel rods each about 18 in. long and half an inch in diameter, jointed to the next by two small, flat, steel links. The windlass employed is polygonal, and thus slipping is altogether avoided without any peculiar mechanical expedients. Mr. Hall's drawings illustrate a system of working by which the engine (or engines) rests stationary outside the field to be ploughed, two anchors being employed, between which the implement travels. The anchors are supported on small iron wheels, which proceed along the headland automatically, on rails, consisting simply of 2½-in. angle-iron bars of such a length that they can be conveniently moved by one man. The flanges support the anchor wheels, and prevent that important member of the system from yielding to the strain of the rope. The angle irons are retained in position by broad stakes driven into the soil, against which they bear. The anchor man takes up the bars as they are left behind, and, having previously driven the stakes, puts them down in position to receive the wheels as the anchor advances. We have, before now, spoken in terms of praise of Mr. Hall's system, which is we believe, really one of the best yet developed. Its economy is not its least recommendation; while its simplicity, and the ease with which the mechanism necessary, can be managed, and repairs effected, render it eminently suitable for situations where the aid of skilled labour is obtained with difficulty. Mr. Hall's apparatus is displayed in the stand of Messrs. E. R. and F. Turner, who exhibit a good 7-horse portable engine and thrashing machine; mills of various kinds; and Ager's patent digging machine—an ingenious implement, which is said to perform its work very satisfactorily.

Messrs. T. B. Brown, and Co., exhibit very excellent specimens of wire fencing, wrought-iron hurdles of various kinds, field gates, weighing machines, domestic flour mills, &c., for the manufacture of which the firm enjoys a high reputation. The entire display is very creditable.

Messrs. Wallis and Haslam exhibit a 4 ft. 6 in. combined thrashing machine, fitted with Coulson's spring hangers, and a hummeller resembling Underhill's elevator in its general details—the fan is not used as an elevator, however, its duties being confined to the hummelling of the grain, and the supply of a subsidiary blast for cleaning the corn. In this stand we noticed a very ingenious seam-presser and plough combined, which is well spoken of. This firm has lately purchased the patent for Lansley's single wheel steerage for drills, &c., which we recommend to the attention of agriculturists.

We had our attention called here to a well-finished model of Wallis's patent system of raising and delivering goods one, two, three, or four hundred feet, over intervening ground or buildings, without interference with the traffic beneath; thereby saving the whole of the expense of trucking or backing, as now in use. If goods are taken from a ship's hold, or from a railway truck, to the upper floor of a granary or mill, some power, by application of a strap to a rigger, is required; but for loading out, the apparatus is self-acting. The invention is partially carried out, and may be seen at work at Wallis and Thomas's flour mills, at Basingstoke, where the intervening space traversed is 160 ft., comprising a timber wharf, belonging to the London and South Western Railway Company, and a public footpath. The principle involved

is that of hauling the loaded sacks up an inclined wire rope.

Mr. Steevens exhibits a complete set of apparatus for cultivating land by steam power, and a four-furrow balance plough. We have already stated that novelties are few and far between in agricultural machinery just now. This plough is one of the few; and, unlike many other innovations, it is really good as well. It is not easy to describe the peculiar arrangements in which the merits of the instrument exist. As a whole, it resembles Fowler's plough in general appearance, but its construction is totally different. The main frame is fixed, while the two plough bodies, carrying four shares each, rise and fall beneath it, in such a manner that all the shares of each set enter or leave the ground at the same moment, and at the same velocity, in obedience to the hand of the ploughman. The steering apparatus is exceedingly simple—namely, a rack and pinion, turned by means of a wheel and a horizontal screw 2 ft. in length in a brass box, fixed in the centre, and geared by four bevel wheels. There are, also, two powerful rods at each end of the plough; which, when fixed in their proper position, keep it firm in its work, and prevent it from jumping, either on even or uneven surfaces, or up hill or down. There are no slades used with the mould boards, so that the draught is materially diminished, and the bottom of the furrow is unglazed. The plough is supported on four wheels, three on the land and one on the furrow side. The main wheels on which the principal part of the weight is borne, are 5 ft. 6 in. high, this large diameter giving lightness to the draught.

Messrs. Ransome and Sims exhibit an 8-horse portable engine, thrashing machine, ploughs, &c., and their patent rotary screen, which we know, by practical experience, to be one of the best, if not the best, of its kind.

In the stand of Messrs. Marshall and Son, we noticed an 8-horse portable, of very good design. The piston rod, slide bars, valve rod, &c., are of Bessemer steel, worked to a beautifully fine face. Everything about this engine is thoroughly well done—the oil cups, forged on the connecting rod head, &c.; the eccentric rods are dovetailed into the brasses, in addition to the usual bolts; all the nuts are case-hardened; and the fly-wheel balanced by coreing out the rim. Altogether. We regard this as a most favourable specimen of the agricultural engine, while the price (£225) is very moderate.

Messrs. Barrett, Exall, and Andrewes, have a good display of implements, the engines being peculiarly well finished. The stay bolts in the fire boxes of those shown are, however, rivetted over into countersinks, so that it is impossible to say how widely they are spaced by external examination. It is rather remarkable, that not a single engine shown is fitted with the injector; the use of a short-stroke plunger pump being universal. We presume that Mr. Giffard's invention is found to be too delicate in its action, and too whimsical in its temper, to be entrusted to the ordinary farm labourer.

Messrs. Brown and May, of Devizes, show a very neat 8-horse portable, with a steam belted cylinder. At Worcester, a similar engine, by this firm, gave a higher duty per lb. of coals, than any other commercial engine exhibited. In the same stand, is a little vertical 2½-horse engine, self-contained, which is a marvel of cheapness at least; the price being only £60.

We should neglect our duty did we omit to mention the Victoria self-raking reaper, exhibited by Messrs. Crosskill and one or two other firms. The machine is suitable for cutting any cereal crop, and delivering it at the side in neatly formed sheaves. The automatic delivery is very simple, and may be varied to suit any crop. It consists of a series of rakes and arms, which revolve round a vertical shaft under the guidance of an irregular waved ring or cam, in such a manner that they bring the corn forward to the knife, and subsequently deliver it, when cut, at the side of the machine.

The total number of stands in the Hall devoted to machinery is 126, from which we have selected all that was most worthy of note. The entire display is, on the whole, very creditable to the skill and energy of our agricultural engineers. Their designs generally show more taste and more forethought year by year; and the result is a mechanical fitness, so to speak, which adds both to the efficiency and durability of the class of machinery which they undertake to construct. As a class, they labour under disadvantages from which their professional brethren, following other pursuits, are exempt. Not only is their machinery severely tried by the exigences of situation; but it has commonly to go through the ordeal under the guidance of unskilful men, who scarcely possess the intellect or training necessary to qualify them for meeting emergencies after the best fashion.

The success with which the agricultural engineers of Great Britain have encountered difficulties and obstacles of no trifling importance, entitles them to a far higher rank than that which they hold. Too great a devotion to a struggle for mere commercial success, has hitherto operated disadvantageously; while the system of turning out "racers," encouraged by an erroneous method of awarding prizes at agricultural shows, has done anything but tend to raise the social status of the class, in the estimation of the scientific world. Matters are much better in this respect than they used to be; and a very few years of progress will, we trust, banish remaining abuses, and place all the operations of the agricultural engineer in a proper aspect, both as regards himself, and the world at large.

THE EXTENSION OF STEAM TILLAGE.

THE agricultural engineering fraternity appears to carry out as vigorous a propaganda as that of the disciples of St. Ignatius de Loyola. Their missionaries are sent out to convert the farmers of every civilized country. Like other prophets, their powers of conversion appear to increase in the direct ratio to the distance of the field of their exertions from their native country. The foreign missions seems to have the most success, and the benighted lands of Russia and Egypt appear to be more receptive of agricultural truth than the United Kingdom of Great Britain and Ireland. Last Wednesday afternoon, however, a meeting was held at St. James's Hall, for the special conversion of the British farmer to the doctrines of steam tillage.

Taking advantage of the great concourse of agriculturalists from all parts of the country to the Smithfield Club Show, the General Steam Cultivation Company were thus enabled to expound their intended course of action before a befitting audience. Though not very numerously attended, the meeting could well be called select, as the gentlemen present were evidently all more or less practically interested in the question of steam ploughing—speakers of all ranks, from the Earl of Suffolk, to small tenant farmers—agriculturists from Australia and the West India dependencies—alternately gave their opinions to the meeting, or made inquiries of the more experienced users of the steam plough. The intended operations of the "General Cultivation Company," are substantially those of a Loan Company. It proposes to furnish owners and farmers of land with all kinds of steam machinery, the price of which is to be repaid to the company in annual rates extending over periods varying from three to seven years; one-fourth of the price of the machinery being paid down by the purchaser within three months of the date of the agreement. The last amount would evidently be covered, in most cases, by the sale of the horses and horse implements, superseded by the steam machinery. But as a farmer, name unknown, very sensibly pointed out, even this outlay could not be incurred by the small tenants of, say, 50 acres. He advised the company to sell machinery in the way proposed to the now numerous class of hirers out of steam-thrashing machinery; and the company would, no doubt, find it to their advantage to adopt this plan.

It is to be hoped that the company will be in every way successful, and numerous similar bodies will then at once spring up in all parts of England. Nothing else is needed to make steam ploughing as general as steam thrashing. Even if we had not had some practical experience in the matter, the facts and figures cited at this meeting—by Mr. Holland; by Mr. S. Hutchkinson, the author of a noted essay on steam cultivation;* by Mr. Williams, of Abingdon; the Earl of Suffolk; Sir George Jenkinson; and by others, more especially by Dr. Vœlker—would be sufficient to convert us, as well as the most sceptical and conservative agriculturist. One gentleman alone seemed still undecided. "A Suffolk land-owner, he had undergone in 1853, dire and dearly-bought experiences with a thrashing machine and engine. This engine was worked out in a few months, and his thrashing machine would scarcely work at all." Has not this gentleman eyes to see and ears to hear, now in this year of grace, 1863, the universally used thrashing machine? Does it not occur to him that his engine and thrasher must have been mismanaged; that his unpractised farm labourers probably burnt out the fire-box by letting the water get low, and were unable to arrange the intricate riddles and screens of his 1853 thrashing machine? Can we conceive of a man getting up ten years hence, when steam ploughs will be as much in use as thrashing machines now are, and complaining that his ploughing engine and tackle got out of order from want of attention? The experience of this gentleman is an instance of one of the difficulties to be encountered in the introduction of machinery. Lord Robert Montague's experience, as related by himself to the meeting, is another instance, but of a different kind—that of foregone prejudice. "Until he had lately seen one of Fowler's ploughs 'racing' over a field, he did not believe steam cultivation to be more than a visionary scheme." Such is the fate of everything new in engineering. Something visible, and palpable, and successful must be placed before the unthinking multitnde of all classes—anything less tangible is prejudged to be impossible.

Several resolutions were carried *nem. con.* at the meeting. We fully agree in those

* "Fire and Water *versus* Corn and Hay:" an Essay on the Effects of Steam Cultivation," by SIMON HUTCHKINSON, Third Edition. Fourth Thousand. London: Simpkin Marshall and Co., 1863.

bearing upon the intended mode of procedure of the company. The first resolution has been endorsed by every user of Fowler's steam tackle—"That the cultivation of the land by steam is now proved to be an advantageous and highly economical process; and that the machinery now used for this purpose is of a character sufficiently perfect to be recommended for the use of practical farmers." The substitution of an untiring, ever-working, coal-fed apparatus, consuming its food when at work only, for a costly corn-and-hay-fed fragile, ravenous, flesh-and-blood animal; the use of an implement working with such speed as to render the agriculturist independent of the seasons; the possibility of attaining a tilth so deep as to increase the produce by one-fourth; the improvement of the land by the complete burying of the weeds; the avoidance of the "pan" always caused by the treading of a team of horses and men, never weighing less than two tons; are not the only advantages—great as they are—of the steam plough. Mr. Williams, a practical farmer, and Dr. Voelker, both in their different ways, pointed to the great saving in costly manure effected by a deep tilth in clay land. The strong clay lands of England can now be worked at as little cost as light land by horses. It is often superficially remarked, that light land cannot be more profitably worked by steam power than by horses. It is the case, that the cost of ploughing per acre is not less on light land with steam. But the work can be done with greater speed on light land, from there being little strain on the rope, and from a larger plough being applicable. As was well observed by Lord Robert Montague, no earthly power can increase the area of the country in the ratio of the increase of population; but the cubic contents and productive power of the land under cultivation, is to be increased by a deeper tilth than can be obtained by animal force; and by means of railway communication, the coal to be substituted for the corn and hay required to develop animal power, is now brought to every English farmer's door.

Our opinion of the practical value of Fowler's tackle is even higher than is expressed in the resolution we have quoted. Not merely is "the machinery sufficiently perfect to be recommended for the use of practical farmers," but we say that, humanly speaking, Fowler's tackle is not to be improved. The construction cannot be much cheapened. It is of no use to wait. It is of no use to expect anything better. Steam tillage is no longer "in its infancy." Steam ploughing was attempted 250 years ago; Wildgosse, of the 17th, preceded Fowler of the 19th century. The only plans at all successful, were those of Heathcoat and of the Marquis of Tweeddale, and they both used contrivances similar to those of Fowler; but they lacked Mr. Fowler's perseverance, and were less aided by the mechanical powers of the present time. Romaine's rotary digger was freely tried, and as completely found wanting. Nearly a quarter of the power was consumed in merely carrying rotary diggers over their work. Halkett's plan of carrying about a ponderous bridge-platform and engine will never supersede the steel-wire rope. Boydell's elephantine engine will never again be seen dragging half a dozen hand-ploughs at its tail.

Of course we do not suppose that the doctrine of the finality of reform can ever be accepted in an engineer's workshop. Many of the details will, doubtless, be improved. The engine may be simplified; it may be made to consume less fuel. Much power is consumed by the clipping pieces of the hauling drum: it is evident that the tackle itself can be only improved in two directions; by diminishing the waste of power due to the bending and friction of the rope, if it be possible, or by improving the form of the tilling implements. Some highly valuable dynamometric experiments made by Messrs. Morton and Harrison have determined the furthest tether to which these improvements may be carried. From the published account of these experiments we extract the following details:—A four-furrow plough, cutting 8 in. deep at a speed of three miles an hour, was found to exert a total strain of 36 cwt. on the 700 yards long rope, which was stretched between an engine and anchor 350 yards apart. The slack rope was found to be strained up to 7½ cwt.; and, subtracting these 7½ cwt.—equally exerted on both sides of the clip drum—from the total strain of 36 cwt., 28½ cwt. remain due to the total draught. Mr. Morton found that no less than 95 per cent. of the total draught was applied to dragging the implement; only about 1½ cwt. being consumed in the draught, &c., of the rope, and in moving the anchorage. The draught of the plough, when out of work, was found to be 2¾ cwt.; leaving 24¼ cwt. or 86 per cent. of the total draught to be employed in turning the furrows. We do not suppose that any other arrangement could be made to consume much less power. And yet an able speaker, at the meeting, complained that the ploughing apparatus was not light enough nor cheap enough, and that it consumed too much power. This gentleman came from Antigua, and he stated that he had seen Fowler's steam plough effecting wonders in the island of Barbadoes, and at Demerara. At Barbadoes, they were ploughing 12 in. deep with a Fowler's tackle, and the effects upon the sugar crop he stated to be wonderful. At Demerara, the engines were placed on the canals, in punts, and much difficulty was experienced from the rope cutting into the banks of the canal. This gentleman's expectations seemed to be greatly raised by a paragraph in the *Times*, to the effect that the French Emperor had given an order, in Paris, for a dozen steam ploughs, of a marvellously light and cheap structure. This intelligent colonist seemed to be as yet unaware of the immense distance between the truth of a paragraph in the *Times* and a mechanical improvement. Another gentleman, who said that "he had the misfortune to be an Irishman and an Irish landlord," stated that he expected to see the salvation of Ireland through the steam plough; that it would remedy the depopulation of the country through the everflowing exodus to America, and that the peasants remaining in the country would be much raised from their present status by the facilitated cultivation of the soil.

We wish every success to the undertakings of the General Steam Cultivation Company.

THE ORDNANCE REPORT, 1863, CONDENSED; AND CONCLUSIONS FROM IT.

No. V.

THE ARMSTRONG SYSTEM.

GOING back to 1854, when Mr. Armstrong first presented himself to the Government in the character of an artillerist, and carefully tracing his proceedings since that period, the Select Committee on Ordnance came to the conclusion that Mr. Armstrong was to be regarded as the projector of a system of artillery. After receiving impartially the voluminous evidence brought before them for the purpose of determining the nature of the Armstrong system, the Committee represent in their report:—1. "That Mr. Armstrong proposed a method of constructing a gun which rendered it capable of enduring the strain to which rifled ordnance is submitted; 2, that Mr. Armstrong introduced to the notice of the Government a plan of breech-loading; 3, that he adopted the old polygroove system of rifling, which involved the coating of the projectile with soft metal."

The Committee, it must be admitted, exercised a sound discretion in defining the "system" in these general and cautious terms. They are the precise words of the Report. They state the heads under which the combination of construction, which "came to be viewed as the Armstrong system," is to be considered.

That it may not be supposed we are influenced by any bias against the system, we will let the witnesses, including Sir William Armstrong himself, speak on the points above stated, before we offer any comment.

The Report informs us that, in the construction of the Armstrong gun, the principal feature which renders it capable of resisting the strain to which rifled ordnance is submitted, is the application of the coil system. It has been inferred, but nowhere stated in the evidence, that Mr. Armstrong had in laying his plans before the Government claimed that method of strengthening guns as his invention. However that may be, the following testimony affords abundant proof that there is no foundation for such a claim:—

Mr. Whitworth (No. 1,204 to 1,213): "The coil principle is not Sir W. Armstrong's invention; he was not the first inventor. Many years before him, patents were taken out for the coil principle. I used the coils in 1855. The barrels of fowling-pieces are coiled. As far as the tube is concerned, it is made in the same way as the old fowling-piece barrels."

Mr. W. W. Hulse (No. 1,286): "In 1855, I made hoops of welded coiled iron." (No. 1,358): "The hoops were made by simply twisting a bar of iron, in a heated state, around a stud or pin placed in in the centre of the smithy, and then forming a coil, and afterwards getting it up to welding heat and hammering it into a coil or hoop; that was Mr. Bamforth's plan." (No. 1,359): "In the small model gun (produced before the Committee), there were instituted three experiments with a view to ascertain the best mode of constructing the hoops, so as to give the greatest strength, with the same quantity of metal. One mode was that of welding the hoops together diagonally, as a band of iron; the second mode was taking a riband of iron, and folding it round, and welding the ends to the body; the third plan was taking the band of iron, coiling it round spirally, and welding it endwise; then the hoops were subjected to inside pressure, so as to ascertain which would yield first; and the spirally made hoop stood the greatest pressure." (No. 1,360): "Was that model (referring to a small gun produced by the witness) constructed of hoops made from coils made from a riband of iron on the same principle as Sir William Armstrong's are now made at Woolwich?"—"Yes, precisely." (No. 1,363 to 1,367): "Were the hoops made for the gun?"—"Yes." "How were they made?"—"Variously; those made by Mr. Bamforth were made as explained by Mr. Whitworth, coiled spirally, for I went to Mr. Bamforth myself from Mr. Whitworth, gave directions myself, and conferred with him on the best plan for carrying them out."

Mr. Vivian: "That was in 1855?"—"Yes."

Mr. Baring: "Therefore those hoops were made, not by Mr. Whitworth, but under his directions, on precisely the same principle and system as the hoops made at Woolwich?"—"They produced precisely the same results, but they were not made by precisely the same means."

"Will you explain the difference to which you point to the Committee?"—"The difference in means was, that at Woolwich they had a furnace 90 ft. long, which we could not obtain in any manufactory then existing; they had coiling apparatus and steam hammers purposely adapted to the work; they had a large plant established, which could not be had by us." (No. 1,369): "No large guns were ever made without coiled hoops by Mr. Whitworth; nothing above 12-pounders." (No. 1,370): "Those coiled hoops, I suppose, being not only iron made into a coil, but on precisely the same principle as the Armstrong coil?"—"On precisely the same principle as the Armstrong coil, only that the hoops were never welded to each other; the hoops made at Woolwich are turned and recessed, put into an hydraulic press, and then put into a furnace and welded together; that plan was never adopted by Mr. Whitworth." (No. 1,371 to 1,381): "There was a limit to the length of the hoop in our establishment, which was not experienced at Woolwich." "If they made two hoops at Woolwich of a given length, they could afterwards, with their facilities, weld them together so as to make one continuous length, dovetailing them together. The small hoop, made under Mr. Whitworth's directions, was made of a coil, forged endwise and welded. It was constructed of a bar of iron twisted round and round, so as to make it spiral, and it was welded endwise." (No. 1,362): "The hoops in Sir W. Armstrong's guns were connected longitudinally—they were welded together. Mr. Whitworth prefers to connect them together by a screw."

Mr. Whitworth (No. 1,311): "The difference between Sir W. Armstrong's gun and mine, in respect of coiled iron, is, that I have always used an inner tube, which has always been made from a solid bar not coiled. Sir W. Armstrong has used an inner tube of coiled iron, as well as the hoops." (No. 1,312): "Sir W. Armstrong, in a letter, stated, that when he did make the gun with an inner tube, made out of a solid forging instead of from coiled iron, he did not approve of it." (No. 1,316, 1,317): "I have never yet made a gun with a tube of welded iron; I never would think of doing so; I prefer a mild steel, or what is called homogeneous iron." (No. 1,318): "The Armstrong guns are entirely composed of coiled iron welded. The inner as well as the outer hoops are welded coiled iron." (No. 1,320): "There is nothing new in the system of coiling iron to make guns—that has been practised for many years with the outer hoops." (No. 1,322): "There is no novelty in getting the requisite strength for a gun by using coiled iron; it is quite old." Captain Blakeley (No. 4,627): "Is your system of coiling the same, or does it resemble that of Sir W. Armstrong?" "I cannot see any difference. The manager of the Butterley Company, in Derbyshire, which made my guns in 1855, who accompanied me to the Woolwich Arsenal last year, or the year before last, said in my presence that the system on which they were making the guns there, was identically the system on which they had made guns for me in 1855." (No. 4,642): "Therefore, at that time, your idea would be that the external portion of the gun should be made of coils and the inner tube of steel?" "Yes, exactly so; and that is what Sir William Armstrong's gun is now." (No. 4,645): "The real essence of Sir W. Armstrong's gun and of my gun does not lie in the use of those coils, but in the manner in which the outer coils are made to compress the inner ones, so as to make the two layers act in unison in resisting the strain. This is very clearly explained by Sir W. Armstrong in his letter, of the 14th July, 1855, in the Blue Book of last year."

We have given the evidence relating to the coil system at some length, that the principles of construction involved in it may be understood. Notwithstanding the concurrent testimony of competent and trustworthy witnesses, Sir W. Armstrong, without venturing to maintain that he is the inventor of the coil system, which would be a manifest absurdity, lays claim to originality of design in the mode of constructing the coils. As the fairest way of testing the validity of this claim, we will let Sir W. Armstrong speak for himself. In answer to the Chairman's question (No. 3,163), Sir W. Armstrong says, "I should wish to run through a brief history of the whole of the transactions, with respect to my system of rifled ordnance, so that the Committee may have before them the entire case, in a compact form." He then makes a detailed statement of his views for constructing rifled guns of the required strength and of the measures he took to carry these views into effect. With reference to the coil system, the following are his observations:—"The substitution of elongated solid projectiles for spherical bullets, is an essential step in the attainment of very extended range in artillery practice; but the lengthening of a solid projectile involves the necessity of strengthening the gun, to enable it to resist the greater intensity of force, which becomes necessary to give the required velocity, and this object can only be effected, consistently with lightness, by constructing the gun of steel or wrought iron, instead of cast iron or bronze." "There is also much uncertainty in the lateral strength of wrought iron or steel, because the flaws or imperfections of welding, which exist in all thick masses of those materials, almost invariably run in the direction of the length, and in general, therefore, only detract from the strength in the transverse direction. It is for these reasons that the barrels of muskets and sporting guns are formed by twisting long slips of iron into spiral tubes, and then welding together the edges, by which means the longitudinal length of the slips becomes opposed to the explosive force of the powder, and the weldings being transverse with the bore have no important influence in lessening the strength of the barrel."

Sir W. Armstrong, after referring to the failure of his attempts to make gun barrels of sufficient strength by forging wrought iron into the usual form, states—"The results obtained in this manner showed, as had been apprehended, great uncertainty in the strength of the material, and rendered it impossible to define the thickness necessary to resist a given charge of powder. I felt compelled, therefore, to dismiss this mode of construction, and to adopt another, more correct in principle, but more difficult of execution."

He next describes his plan of making an inner barrel of steel, and continues—"The parts surrounding the steel centre consist of twisted cylinders of wrought iron, made in a similar manner to gun barrels, and, being shrunk upon the steel, they are in that state of initial tension which is necessary to bring their entire strength into operation." The gun is described as having a steel barrel, and the external parts are represented as coil. The mode of breech-loading is also described—"That was the first gun delivered in 1855, which was accompanied by the Report, from which I am quoting this description and these drawings, therefore, furnish a complete definition of what the gun really was. It was a gun with a steel tube, surrounded with coiled cylinders similar in every respect to the tubes of gun barrels. Now the peculiarity of that gun was not its being merely a built-up gun, because built-up guns are of very ancient date. In fact, I have no doubt that the original construction of all guns was by building-up. It was not merely a hooped gun, that is to say, a gun strengthened by rings, because rings give only circumferential strength, and no longitudinal strength; but that gun was peculiar in being mainly composed of tubes, or pipes, or cylinders, formed by coiling spirally, long bars of iron into tubes, and welding them upon the edges, as is done in gun barrels. Now, whether any one had conceived that idea before is beyond my power to say; but I feel assured that no gun, up to that time, had been actually made upon that principle. The whole difficulty lay in the making. It is very easy now, with all our knowledge and experience, to define how such coils are to be made; but at that period it was a very difficult matter to accomplish, and it was not until I had made very many unsuccessful attempts that I succeeded in satisfactorily carrying it out."

We here have from Sir W. Armstrong a detailed description of the effect of forming tubes with slips or bands of iron, spirally coiled and welded, in increasing the strength of the barrel; but that effect was well known to gunmakers long before Sir W. Armstrong's time. At the period (1854, 1855, and previously) when the attention of artillerists was first drawn to the value of rifled ordnance, Mr. Armstrong was not the only or the first person who perceived the importance of applying the spiral coil principle—long before in general use for small arms—to great guns. In taking credit to himself for this adaptation of a well-known principle, he assumes a merit to which he has not the smallest claim—not even that of priority of adaptation. In his diffuse statement, of which we have only given some extracts, he argues his own case with no small amount of self-sufficiency—as if all the artillery world but himself had been standing still. This notion, which seems to be a fixed delusion in his mind, and for some time infected the War Department, is completely dispelled by the evidence in the Report, proving that the minds of other persons, as capable and more practical than Sir W. Armstrong, were at work on the same ideas, not only simultaneously, but prior to his first experiments. The real difference between him and them was, as we have proved from the Report, that he had the patronage of the Government, and they had not. If the opportunity, freely accorded to Mr. Armstrong in 1854 and 1855, of making experimental guns for the Government, had been afforded to the Mersey Steel and Iron Company, Mr. Whitworth, Captain Blakeley, and others, they too would have manufactured trial guns for the War-office on the coil system. By this competition of mechanical talent, properly encouraged by the public authorities, some of the blunders into which they, under the guidance of Sir W. Armstrong, have fallen, would have been foreseen and avoided, and the country would have obtained a far more effective system of rifled artillery than it now possesses.

(To be continued.)

LONDON ASSOCIATION OF FOREMEN ENGINEERS.

On the night of Saturday, the 5th inst., the ordinary monthly meeting of the above Society took place. Mr. J. Newton, of the Mint, filled the chair, and the attendance of members was numerous. It had been arranged that Mr. Stanley should read a Paper on a "Substitute for the Slide Link Motion;" but, although that gentleman had prepared his Paper, as well as models and diagrams to illustrate it, he was too seriously indisposed to attempt the arduous task, and the reading was postponed. Many new members, however, were elected, and the Chairman subsequently directed, in a few feeling remarks, the attention of the Society to the painful circumstances which had attended the death of the well-known author of many mechanical and scientific works, William Templeton. It was needless, he said, for him to expatiate upon the claims which Templeton had upon the mechanical communities of this and other countries. His books were text-books; and his scientific memoranda, guides to all *young* mechanics especially. Templeton, however, had died in extreme poverty. The booksellers had reaped the fruits of his labour, and his widow inherited honour,—and destitution. As Templeton had been an honorary member of that Association, Mr. Newton thought that a small sum—they could not afford a large one—should be voted from their funds for the benefit of the widow, and that in addition a voluntary subscription should be opened up in her behalf. It might not be improper to furnish some brief notes in reference to the life of William Templeton; and possibly if the scientific press—ever ready to assist in such cases—were to give them publicity, attention would be drawn to the matter of the widow's destitution beyond the walls of that room. Mr. Templeton was born at Caltrine, Ayrshire, on the 9th of February, 1796. He was the father of a large family—namely, seven sons and three daughters—of these, six of the sons were unfortunately dead. Templeton was for some time a Chief Engineer in the Royal Navy—in fact, for five years. He left the service, however, and, for one year subsequently, was located in the Island of Java. Failing health compelled him to leave that place, and he next went to Australia. While there, Templeton superintended the erection of a breakwater at Port Elliot, and wrote a small work, known under the title of the "Commercial Prompter." On returning from Australia, he devoted himself to scientific literature. His principal works are the "Millwright and Engineer's Pocket Companion," "The Steam Engine Popularly Explained," "Mathematical Tables," "The Workshop Companion," "Practical Examinator," "The Engineer's, Millwright's, and Machinist's Practical Assistant," and others of a like character. The poor author died in London on the 12th of August last, aged and destitute.—At the conclusion of these remarks, Mr. Blackett explained the circumstances attending the last hours of Mr. Templeton, and confirmed the Chairman's statement as to the sad condition of his widow.—On the motion of Mr. Ross, it was agreed to devote the sum of £5 from the funds of the Association for the relief of that lady, and, at the same time, to open a subscription list in her behalf.—Finally, a committee was nominated to receive contributions to that end. The committee comprise:—Mr. William Ross, Messrs. Rennie's, Holland-street, Blackfriars; Mr. John Ives, Messrs. Henry Grissell and Co., Regent's Canal Iron Works; and Mr. Sanson, of 20, Cannon-street, City, either of which gentlemen will be happy to receive any sums, large or small, in trust for the widow Templeton.—It is to be hoped that throughout the country there will be a generous response to the appeals of the Committe of the Association of Foremen Engineers of London.

The Adriatic Mills in Worcester, Mass., are driven by a Corliss engine, which has a belt on it 30 in. wide, 114 ft. long, and double throughout.

MACKILLOP'S SYSTEM OF CLEANING SHIPS' BOTTOMS.

Fig. 1.

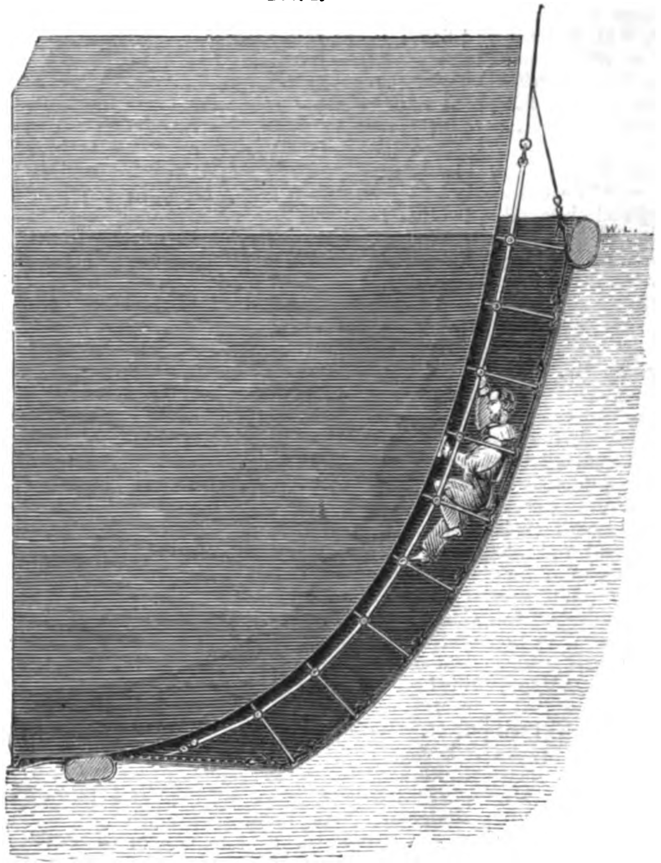

Fig. 2.

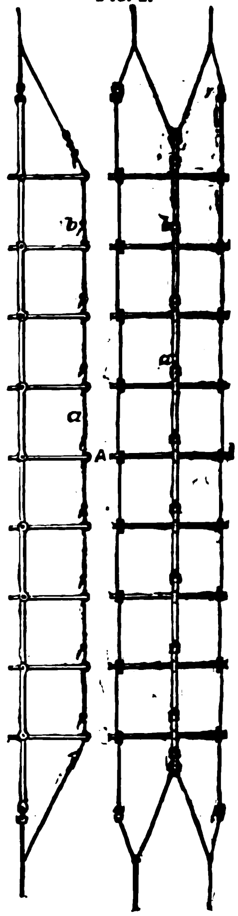
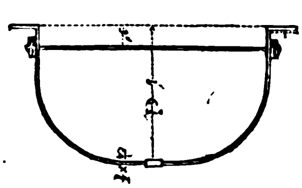


MACKILLOP'S SYSTEM OF CLEANING SHIPS' BOTTOMS.

The machine is made of canvas and india rubber or leather. The portions A, in the accompanying engraving, are air-tight, and inflated after the machine is submerged and placed under the ship in the desired position. An iron ladder with arched back pieces, fig. 2, B, is lowered over the ship's side with a guide rope under the keel, brought up on the opposite side, over which the flexible machine is placed and inflated. Should a coffer-dam be wanted, the air cylinders A and A, on either side of the ladder, will by the pressure of the air adhere close to the bottom and side of the ship, and admit of the water being pumped out of the dam thus formed in the centre of the canvas machine.

Should the machine be simply wanted for re-

Fig. 3.



moving grass and incrustations from the bottom, the ladder is left out, and the lining of the machine brought close to the ship's side, between which unslaked lime and other substances are introduced from the water's edge, the action of which, in the process of slaking, will destroy animal and vegetable life. When this has been done, the machine must be moved along the bottom by the guide and keel ropes, which will remove at the same time all the foul matter previously acted upon by the lime. This process may be repeated along the whole length of the ship, after which the ladder may be put in position and portions of the bottom examined.

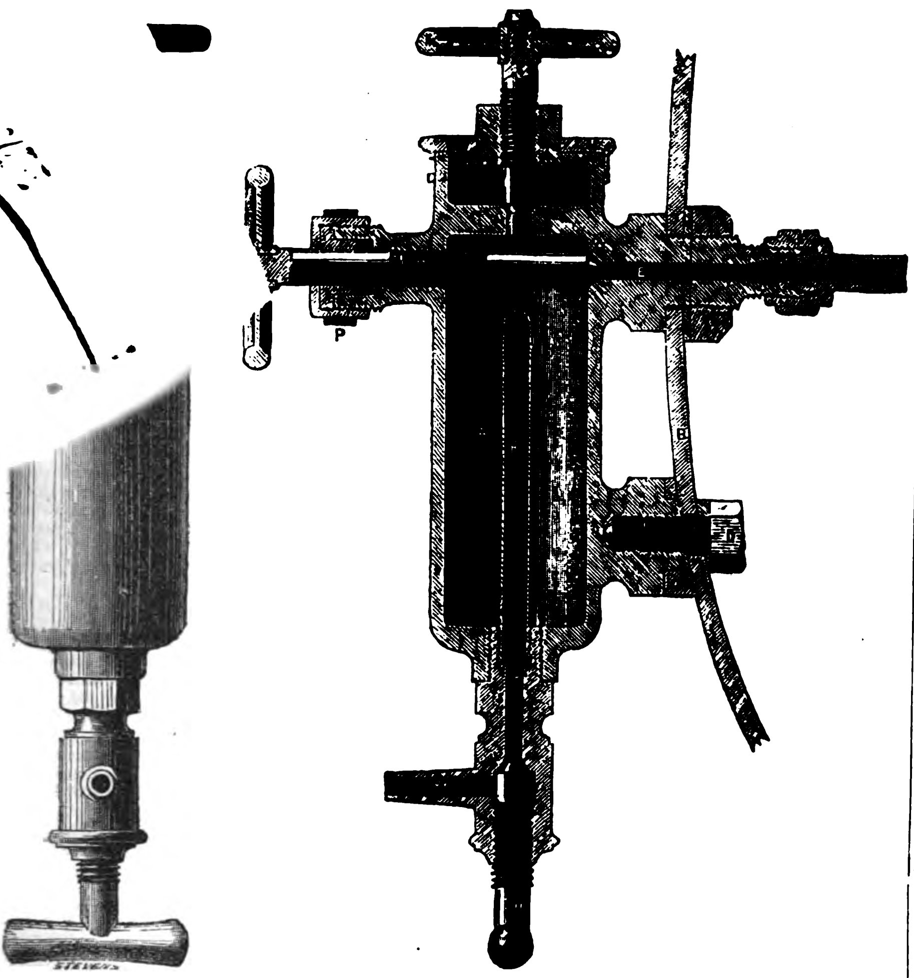
Should a ship at any time, having one of these machines on board, spring a leak, the machine may be quickly and easily placed over the leak and inflated, when the adhesion will not only be sufficiently secure to stop the leak, but it will allow of the ship making the remainder of her passage with very little detriment to her speed. The machine, when inflated on the water, may be used as a pontoon or raft by laying a few planks across it, when it will carry from 30 to 200 men, according to the class of ship it may belong to.

The Lords of the Admiralty are now having two of these machines prepared at Chatham, under the immediate superintendence of Captain Mackillop.

ROSCOE'S LUBRICATOR, FOR STEAM ENGINES.

This self-acting lubricator has been designed and constructed more especially to prevent the great friction on the slide valves and cylinders of locomotive, marine, stationary, colliery, mining, agricultural, and all other steam engines and steam machines. When the engines are at work, by its continuous action it constantly delivers minute qualities of lubricating matter, to the cylinders and valve faces; whereas, the lubricating cocks generally in use, deliver their contents in a few seconds, and the tallow, oil, or other lubricating matter let in, is necessarily blown away rapidly, and the valves, valve faces, and cylinders are left to work dry after a few strokes. This lubricator, when in use upon locomotive engines, does away entirely with the present dangerous practice of walking on the side of the engine to fill the lubricating cocks, when the train is travelling at a great speed. The lubricators were not designed to save lubricating matter; but wherever used, the engines are found to require considerably less than with the ordinary cocks.

ROSCOE'S LUBRICATOR FOR STEAM ENGINES.

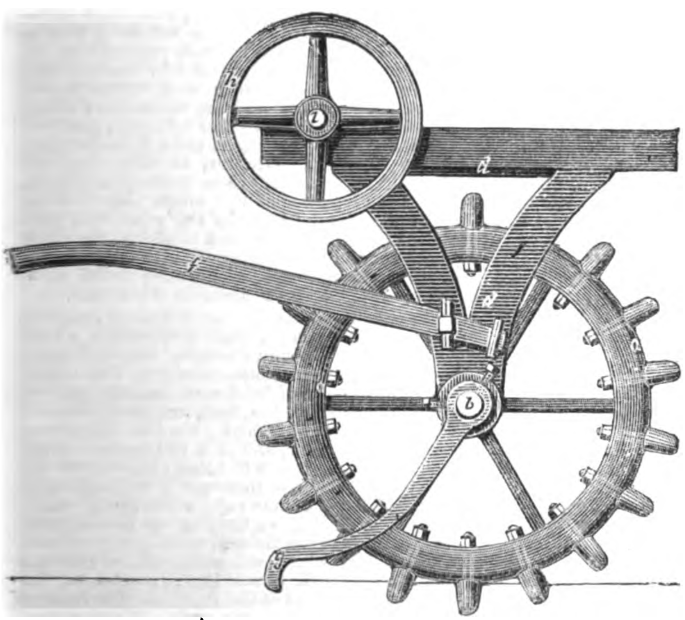


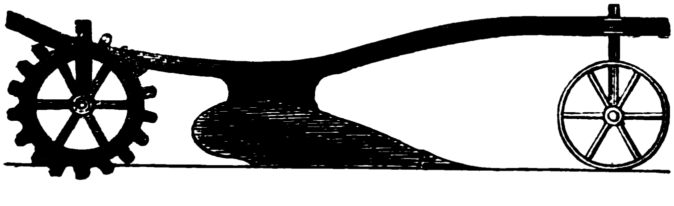
In the accompanying engravings, A is a vessel containing the tallow, oil, or other lubricating matter, and is made of any convenient form and size; but the shape shown in the accompanying drawings is the one usually preferred. When applied to locomotives, it is attached to the smoke-box B by the nut C and the screw D. E is a horizontal tube, cast to the vessel A, and attached by the union F to the pipe G, which communicates with the steam-pipe or chest. H is the cover of the vessel A, and communicates, by a groove, cut through its upper surface, with the hole or slot I, through the collar K, which carries the screw valve L, which is worked by the wheel M, and rests in the valve seat N. O is a regulator-valve, which passes through the stuffing-box P, and rests in the valve-seat Q. R is an air-tube, fixed in the waste-cock S, and communicates by the pipe T with the screw valve U, which rests in the valve-seat V, and communicates externally by the tube W. To put the instrument in action the regulator valve O is shut, and the screw valve U opened, to allow the waste water to escape by the tube W; it is then closed and the cover H turned until the groove communicates with the hole or slot I, the screw-valve L is then opened and the lubricating matter poured into the vessel A; when filled to the level of the tube E, the valve L is closed, and the regulator valve O opened, which allows a portion of steam to enter the vessel A, where it is immediately condensed, and by its gravity descends to the bottom of the vessel, thus displacing a minute portion of the lubricating matter which passes through the tube E and the pipe G into the steam-pipe or chest, and from thence into the cylinders, which are, by the continuous action of the lubricator, kept constantly lubricated, as also the slide valves, valve spindles, piston rods, and all the frictional parts wherewith the steam comes in contact.

When the steam is first let in, it compresses the air in the air-tube R, and the continual alternate expansion and contraction of the air by the action of the steam, keeps up a constant agitation, and with locomotive engines when going down inclines with the steam shut off, the expansion of the compressed air forces out a quantity of lubricating matter into the steam-pipe or chest, which keeps the cylinders, &c., effectually lubricated, until the steam is again let in. The regulator valve O is set to use any required quantity of lubricating matter according to the size of, or speed of an engine—for instance, to use the same quantity with a locomotive engine in 100 miles with a slow train would require the regulator valve to be shut closer than it would for a fast train running the same distance, and it can be as easily regulated to use 1 oz. as 16 oz. of lubricating matter in a given time.

When applied to fixed engines, the lubricators should be placed in as cool a position as possible, on account of the condensation; and in all cases the pipe G (which for fixed engines should not be less than 3 ft. in length) requires a slight descent from the lubricator to where it enters the steam pipe or chest. When in action, the principle upon which this lubricator is constructed prevents the possibility of the water or lubricating matter in the apparatus freezing, even in the coldest climates. The lubricators are made by E. H. Newby, Leicester.

MACHINERY FOR PREPARING LAND FOR SEED.





KING AND MARSHALL'S IMPROVEMENTS IN MACHINERY FOR PREPARING LAND FOR SEED.

THIS invention, patented by Messrs. John King and Henry Marshall, of Warwick, has for its object improvements in machinery and apparatus for preparing land for seed and for harrowing land. In constructing machinery and apparatus for dibbling land, wheels are used with dibbles set on the peripheries, such dibbles are arranged to be adjusted nearer to or further from each other, according to the distance apart at which it is desired to insert seed, and they are also each arranged in such manner as to have a movement when in the land in order to free them therefrom without breaking up and injuring the sides of the holes formed by them. It is preferred that a pair of such wheels should be mounted on the same axle in such manner that they may be readily adjusted to and from each other according to the distance apart it is desired to have the rows. The axle carrying the dibble wheels turns in bearings in a suitable frame; this frame at its centre is capable of turning on a short vertical axis carried on the under side of a frame that is provided with shafts, the frame carrying the dibble wheels is provided with two handles or levers by which this frame can be inclined to the shafts, and the dibbles be thus steered or guided. The shaft upon which the dibble wheels turn is provided at each end with a rod which descends downwards, and the lower ends of these rods, when the machine is at work, enter a short distance into the land, and thus as the machine moves along make lines along the ground; the machine can thus be readily guided by causing the rod on one side of the machine to be moved along the line previously made by the rod

on the other side of the machine. In order that the machine may be drawn along a road or other surface without the dibbles coming in contact with such road or surface, the frame which is provided with shafts carries an axle on its upper sides, which axle is provided with two road wheels; these wheels are of such a diameter that they shall be above the land when the dibble wheels are resting on it; these wheels can, however, be brought on to the land by turning over the shaft frame by means of the shafts, the dibble wheels will then be lifted off the land, as the rod upon which they turn will, by the frame having been turned over, be brought above the axle of the road wheels in place of being below it. In some cases a dibble wheel, such as is above described, is combined with a plough in such manner that the dibbles may run along the ridge or portion turned over by the plough, and prepare the same for receiving seed in the holes formed by the dibbles. In order to harrow land, whether before or after sowing the seed, the patentees construct a harrow of numerous similar parts, each part carrying a tine or tooth, and each of such parts is formed to be connected to two similar parts in such manner that when pressed together they form what may be said to be a rigid bar consisting of several parts; when the harrow is on the land, and the teeth penetrating it, the several parts will be drawn out to a certain extent, by which the parts which carry a row of tines will become flexible, and allow each tine to rise or fall independently of the other tines in the same row. For this purpose the ends of the parts are connected by pin joints, and one end of each piece is made with a slot through it through which the connecting pin passes, and the ends of these pieces are formed to lock into each other when pressed together. At the angles the pieces are formed in the shape of right-angle bends.

Fig. 1, in the engraving, shows a side elevation of a dibbling machine constructed and combined according to this invention.

a, *a*, are two dibbling wheels, in the peripheries or outer rings of which are slots through which the stems of the dibbles pass, and are by screw nuts fixed to the outer rings of the wheels at such distances apart as may be required for the particular crop. The dibble wheels are capable of turning freely on a fixed axle *b*, and they are set to or from each other by means of collars between which they turn; these collars are capable of being slided to and fro on the fixed axle, and of being fixed thereon in any position by set screws, by which the width between the rows of holes made by the dibbles may be adjusted from time to time as may be required. The dibbles are shown to be fixed to the wheels; but this may be varied, and provision made for giving each dibble a rotary motion when in the land, as has before been done. The axle *b*, on which the dibble wheels are mounted and turn, is fixed in a frame *d*, which turns on a short vertical axis *e*; and such frame with the dibble wheels is guided by handles *f*, *f*. To the ends of the axle *b* are fixed rods *g*, *g*, which descend into the land and make marks, so that in returning one of the rods *g* is caused to follow the mark made by the other rod *g* in the previous bout. In order that the machine may, when out of use, be moved along ordinary roads, a pair of wheels *h*, *h*, and axle *i*, are applied at the upper surface of the frame at the back ends of the shafts, and they are brought into use by turning the machine over.

Fig. 2 shows a dibble wheel combined with a plough in such manner that the dibble wheel may act on the ridge as it is formed by the turning over of the land by the plough.

POWER OF WIND AS APPLIED TO FLOUR MILLS.

The application of that violent and intractable element of nature, the wind, to impel machinery, displayed no little boldness on the part of our early mechanics. Windmills are supposed to have had their origin in Germany, about the middle, or towards the end of the 11th century.

It has been often asserted that windmills were first invented in the East, and introduced into Europe by the "Crusaders;" but this is very improbable, as mills of this kind are seldom or never found in the East. There are none of them in Persia, Palestine, or Arabia, and the writer has seen only one in India, which was recently erected. There are several windmills around the town of Smyrna, in Asiatic Turkey, and also on the banks of the Hellespont, in Asia Minor; but it is believed that they were erected subsequent to examples having been presented to them from Europe.

About forty years ago, when the soil of Great Britain was imperfectly drained, the soil was the grand reservoir for storing up the rainfalls and maintaining the uniformity of flow in our water runs; but since the introduction of arterial drainage, our rainfalls are transmitted direct to the sea; and at the present time the mean flow of water in our mill leads is reduced to about 50 per cent. of what it was forty years ago; and it becomes a question whether the application of wind power might not be extended with advantage for the driving of all kinds of grinding mills, also for that of saw mills; reserving our water falls and steam power for purposes requiring a constant and regular supply of power, for which the wind appears to be not so well adapted.

The hilly and undulating nature of Scotland, supplies water falls so numerous and powerful, that windmills have not been much used there for grinding flour. But in the South of England, where the surface is more of the character of flat or slightly undulating plains, windmills are more common, and have generally done well, and realized ample fortunes to many of their owners. When the owners or tenants of flour mills, driven by wind, have sufficient capital, the mill can be employed night and day so long as there is wind; and as comparatively few hands are employed about a flour mill, they might be usefully engaged, during calms, in dressing the mill stones and doing other necessary work in the mill; these remarks also apply to saw-mills, employed in cutting home-grown timber; during calms the hands could be employed in sharpening and adjusting the spare saws, and bringing forward and preparing timber for the mill.

Windmills may be arranged into two classes—viz., those of the vertical, and those of the horizontal construction. Much ingenuity has been expended in endeavouring to improve the horizontal mill, which has never been attended with much success. In fact, machines presenting so much obstructing surface in the plane of motion, while moving in a medium of the same density as that by which they are impelled, must suffer great retardation. From the nature of the horizontal mills little more than one vane can be acting at a time, and the motion of the vanes must of necessity be considerably slower than the moving wind, while in those of the vertical construction all the sails act together, and generally attain a speed much higher than that of the cylinder of wind which impels them. The writer has occasionally travelled 16 miles an hour in the canoes employed on the south coast of Ceylon, when the wind was blowing a pleasant 7 knot breeze; these canoes are 40 ft. long, and are formed of a light timber which the natives call "dombay" wood. The lower part, which is nearly parallel throughout its length, is only 2 ft. wide, and formed of the trunk of a tree hollowed out; and the sides, which are 2 ft. high, are composed of deal 2 in. thick, and attached to the bottom with coir yarn, obtained from the cocoa nut; the ends of the canoe being rounded on the horizontal plane, and sloping considerably outward and upwards on that of the longitudinal and vertical planes. They are rigged with two masts of bamboo, which carry very large lug sails of cotton cloth. The transverse stability of these canoes is obtained by an ingenious appliance termed an "outrigger," which is attached at a distance of 12 or 14 ft. from, and parallel to the canoe, and when sailing with the outrigger on the weather side, two of the boatmen sit upon the outrigger to enable them, by this addition of weight at the windward side, to carry more sail. These canoes are found to travel best without any paint or pitch applied to their bottoms, the immersed part being simply made as smooth as possible. They have no rudder, and are steered with an oar, and with a moderate wind on the beam they often outstrip the fastest of the Peninsular and Oriental Company's steamers.

About seventy years ago, a master mariner, residing at Dunbar, in Haddingtonshire, devised a novel windmill on the horizontal construction. It consisted, essentially, of an upright shaft, which carried four arms, at the extremities of which were four masts, rigged with try sails, and the sheets were adjusted so that the sails might take their proper positions, according as they were acted on by a beam wind, "booming out," or coming up in the "wind's eye." A mill, so constructed, would not possess the important element of durability, as the violent jerks imparted to the sheets would very soon snap them. Several mills on the horizontal construction were in use at the town of Eli, in the litigious kingdom of Fife, at the end of the last century, and were employed in grinding indigo; but they have long since been removed.

In the 12th century, when windmills began to be more common, a dispute arose whether the tithes of them belonged to the clergy; and Pope Celestine III. very considerately decided the question in favour of the Church.

About three or four centuries ago, the avaricious landholders, favoured by the meanness and injustice of government and the weakness of the people, extended their regality or kingship not only over all streams, but also over the very air, and mills which it impelled, so that small proprietors, before erecting a windmill upon their own property, had first to obtain permission from the superior of the province before doing so.

The early mills were immoveable, and could only work when the wind was in one quarter; they were afterwards placed, not on the ground, but on a float which could be moved round in such a manner that the mill should catch every wind. This method gave rise, perhaps, to the invention of moveable mills.

To turn the mill to the wind, two methods have been invented, and are in common use—in the one the whole structure is arranged so as to turn on a post below; and in the other, the roof alone, together with the axle and the wings, is moveable. Mills of the former kind are called German mills, those of the latter Dutch mills. They were both moved round either by a wheel and pinion within, or by a long lever without, which acted as a stay to the structure, and which was sometimes connected at its extremity to a cart wheel, in order to facilitate its movement horizontally.

During the period of the Crimean war, the writer had an opportunity of examining several of the windmills in European Turkey, and also in the Crimea.

Around the town of Eupatoria, in the Crimea, there appeared to be nearly 200 windmills, chiefly employed in grinding corn; and all which were in a workable state were of the vertical construction, and only one horizontal mill, which seemed to have been out of use for at least a quarter of a century. The tower of this mill was built of brickwork, about 20 ft. diameter at the base, and about 17 ft. at the top, and 20 ft. high; the revolving wings, which consisted of six sets of arms, appeared to be about 20 ft. diameter and about 6 ft. broad, fitted with vertical shutters, which were moveable on pivots passing through the arms, the shutters being each about 12 in. wide by 5 or 6 ft. high, and the pivots were fixed at about one-third of the breadth from the edge of the shutter, in order that the wind might open and shut them at the proper time, during the revolution of the wings. About one-third of the circumference of the wings was surrounded by a segmental screen to shelter the arms and shutters while moving up against the wind, and the screen seemed to have been hauled round with ropes, in order to suit the direction of the wind.

The writer also examined one of the most recently erected mills on the vertical construction, which had the words "Moulin Français" inscribed upon the door, by way of recommendation. The tower of this mill was also of brickwork, and appeared to be 18 ft. diameter at the base, and about 15 ft. at the top, and about 22 ft. high; the four wings were about 35 ft. diameter, and of a rectangular shape, about 15 ft. long and 5 ft. broad; the surface exposed to the wind was increased or diminished by the application of canvas sails, whose spread could be raised by reefing or twisting up the extreme ends of the sails when the mill was in a state of rest. The main axle, which was octagonal in form, was constructed of oak, about 15 in. diameter at the neck, and about 10 in at the rear end. The front of the axle which received the arms was square, and the two pairs of arms did not intersect the axle in the same plane, the one pair being in advance of the other; all the arms butted against the axle, and were united to it by side pieces, which were securely bolted to the arms and through the axle, which rendered mortising unnecessary, and preserved the strength of the shaft. The bearing in which the neck of the axle revolved seemed to be formed of some hard wood, probably lignum vitæ, and was lubricated with soft soap and plumbago. The rear

end of the shaft was fitted with an iron gudgeon, about 3 in. diameter, secured by iron hoops and wedges. About the middle of its length, this axle carried a face wheel about 4 ft. diameter, which was constructed entirely of timber; its arms were mortised through the axle, and secured by iron hoops round the rim, which formed the bearing surface for the friction strap or brake for arresting the speed of the mill. The teeth of this wheel, which were about 3½ or 4 inches broad and 4½ pitch, geared into a "trundle," or pinion, about 14 or 15 in. diameter, fixed on the top of a long vertical wrought-iron shaft, about 2½ in. square, which was coupled at its lower extremity to the rhynd on top of millstone spindle, the long shaft being steadied by a bearing near the centre of its length to prevent any jarring or vibration being communicated to the revolving millstones. When the writer visited the mill, the miller was engaged in laying on the revolving stones, he was thus enabled to see the working faces. The millstones were about 3½ ft. in diameter, and were formed of a single stone, similar in appearance to the white silicious burr, obtained from the quarries near Rouen. The stones were not indented with roads and channels to assist in grinding and throwing out the flour, like our flour stones in Britain, but were simply roughened or cracked with the miller's pick. The neck of the millstone spindle was guided by a bushing of hard wood, with the fibre endways, a mode of bushing employed for more than half a century in the flour mills of this country, and which, no doubt, gave the idea to Mr. Penn, of Greenwich, for his mode of bushing the screw shafts in our modern steamers, and which was better than gun metal in situations precluding the use of unguents.

When the mill was set agoing the wings, which were 35 ft. diameter, performed 29 revolutions per minute, when loaded, and the extremity of the sails acquired a velocity of about 3,200 ft. per minute, or nearly 35 miles per hour, and which showed that the "Crim Tartars" knew the importance of letting off their prime movers, a subject not too well understood by some of our British millwrights as yet.

One of the earliest windmills employed in Scotland was erected in 1720, near Dunbar, in Haddingtonshire, and was employed in making pearl barley, and, like a large portion of the barley mills in Holland (of which it was a copy), turned out an unremunerative speculation. With a moderate wind the wings had not power enough to drive the barley mill, and when blowing fresh, they often became unmanageable when the mill was being emptied of barley, and sometimes set the brake wheel on fire. A very simple plan of correcting the variable resistance would be to have two barley mills, and work them alternately; while the one was finishing the barley the other could be receiving its supply of corn, which would render the resisting load nearly uniform, and thus control the speed of the wings.

About the year 1750, Mr. Andrew Meikle, of Houston mill, in Haddingtonshire, effected several important improvements upon windmills, and was the first to devise a really useful automatic appliance for moving the sails so as to catch every wind. This he accomplished by means of a supplementary set of revolving vanes, about 10 ft. diameter, situated in the rear, and at right angles to the cardinal sails; by reducing the motion of the new set of vanes about 5,000 times, through the intervention of wheel-work, and a worm, operating upon a dead worm ring bolted to the mason-work of the tower, he caused the cap of the tower, along with the axle and the cardinal wings, to veer round to the wind, and these smaller vanes were termed the "fan tail." The next improvement which Mr. Meikle attempted was an appliance for reefing the sails when the mill was in motion. His first attempts were not attended with success; but in 1780, he devised a most ingenious adaptation of the centrifugal govenor, viz., a sliding frame on the front of the wings which operate upon rollers placed transversly with the arms, and wound up or reefed the narrow canvas sails when the wings attained too great a velocity, and the unfurling of the sails or increasing their spread was acomplished by a weight which actuated a rod passing through the centre of the main axle, and operated centripetally on the sliding frames, and then unwound the canvas when the motion of the wings was too much retarded. This was the first successful automatic reefing apparatus applied to windmills, and when the wind was not squally imparted to the vanes a precision of motion little inferior to some of our modern steam engines, and by varying the weights for unfolding the sails the power of the mill could be increased or diminished with facility.

In the year 1788, about two years after Mr. Meikle invented the thrashing machine, he applied his improved windmill for thrashing corn; and in order to illustrate Mr. Meikle's ingenuity in erecting windmills for farm purposes, it was his practice always to erect the thrashing mill previous to the wings of the windmill, and as the thrashing drum revolved upwards of twenty times faster than the main axle, the gearing of the thrashing mill formed a convenient crane for elevating the wings after being attached one by one to the axle at the lower part of this circuit. Mr. Meikle was described by those who knew him as possessing much shrewdness and originality in his profession; and, with the exception of the late Mr. Smeaton, and the elder Rennie, who was Mr. Meikle's pupil, was one of the ablest millwrights of his day, and died poor and unrecompensed for his many useful inventions.

In the year 1758, the late Mr. John Smeaton instituted a series of experiments with a model windmill about 2 ft. diameter, in order to ascertain the best shape and angle for the sails of windmills. In the experiments referred to, the air was in a state of rest, and a progressive motion was communicated to the mill by means of a determinate weight acting by means of a cord coiled round an axis with a horizontal arm, at the extremity of which were four small moveable sails; thus the sails met with a constant and equable blast of air, and as they moved round, a cord with a weight affixed was wound about their axes, and they showed what construction of sails and "angle of weather" produced the best effect. From these experiments, Mr. Smeaton concluded that the angle of weather, with the plane of motion should, at the extremity of the sails, be 7 deg., and at the middle 18 deg., and at the centre 18 deg., to produce the best effect. But it is an ascertained fact that the angles of weather, instead of being a constant quantity, should be varied according to the velocity with which the sails are intended to move; when the extremities of the sails are intended to move at 35 miles per hour, the angle of weather should be less than when a speed of only 20 miles an hour is contemplated.

When the sails are planes, and when the extremities move at 30 miles per hour, it has been ascertained that the best angle of weather, with the plane of motion, is 16 deg. A plane, although the best form for the sails of a ship when operated on by a beam wind, and when every part of the sail recedes from the wind with the same velocity, does not apply in the case of revolving sails, where the velocity varies, according to the distance from the centre of motion, and the sails accordingly should be considerably twisted to obtain the same angular velocity, and in order that the moving wind might operate with a uniform purpose over the whole surface of the sails, and the cylinder of wind recede from the sails with a uniform flow. When revolving sails have the form of a plane, the useful area is virtually diminished; and it is a fact worth recording, that the sails of the windmills employed in Holland, have considerably more twist than those in Britain.

With reference to the number of sails it is most advantageous to employ, there appears to be a diversity of opinion among millwrights. Four, however, is the most common number employed in Holland, Germany, and France, and also in the South of England. About twenty years ago, some experiments, on a large scale, were made by a millwright residing near Hull, on a mill which had four sails, which were carried away during a gale. When the mill was re-erected, five sails were substituted, the collective area of which was identical with that of the four sails formerly employed. It was found that the five wings or sails produced a better effect than the four previously employed. This improvement was attributed to the wind escaping more freely from the sails, which produced a more steady action, and less reaction or relaxing of their effect or power while passing the tower. The next experiment had eight radiating or tapering sails, which promised good results; but having encountered a hurricane shortly after its erection, all the eight sails were carried away. Perhaps the principal objection to mills having more than five sails, is their increased first cost, and also the increase of trouble attending their management; so that, all things considered, five sails are found to be the most suitable number in practice; and when a mill with this number of sails is in a state of rest, three of the sails are brought below, and two upwards, in order to lessen the effect of the wind upon the structure.

The conical pendulum, or centrifugal governor, originally devised by Huygens about the middle of the 17th century, to regulate the movement of clocks, was applied by Hooper in 1789 to control the motion of flour mills, impelled by wind. In a windmill, when the velocity is increased by the irregular action of the wind, the grain is sometimes forced rapidly through the mill without being sufficiently ground, and by means of the centrifugal force of one or more balls, which fly out as soon as the velocity is augmented, and by operating on a combination of levers in connection with the bridge of the stone, to increase the power, and to diminish the travel, causes the revolving millstone to descend, and bring it in nearer proximity with the bedstone, thus increases the resisting load on the mill, and this appliance is in some parts of England termed a "lift tenter." In the early part of the present century, William Cubitt (afterwards Sir William Cubitt), then a millwright, residing at Ipswich, devised a mode of reefing the sails of windmills, by introducing moveable shutters on the wings of the mill, which shutters were closed by a governor, like that of the steam engine, operating upon a rod passing through the centre of the main axle. These shutters were suspended on pivots fixed about one-third of their breadth from one side, and when the wind was blowing too strong it opened the shutters and allowed a portion of the wind to pass through them, and so also checked the velocity of the mill. Perhaps an improvement upon Mr. Cubitt's plan might be effected by springs instead of weights to close the shutters, and arranged so that the centrifugal action of the shutter would open them. It is believed that a reefing apparatus so constructed would operate with greater uniformity, and be as sensitive as a properly balanced steam engine governor.

The largest windmills in Britain are to be found at the town of Great Yarmouth, in the county of Norfolk. The wings of some of these mills describe a circuit of 100 ft. diameter, and with a moderate breeze drive six pairs of millstones 4 ft. 6 in. in diameter, grinding collectively 30 bushels of flour per hour. The main shaft is generally constructed of oak, about 3 ft. in diameter, its main bearing being lined with strips of iron 1¼ in. broad, and ¾ in. thick, sunk longitudinally into it, and fastened with screws and spring hoops, so as to form the main journal of the shaft which revolves in a bearing bush or brass. The "stock pieces" to which the arms are fixed are mortised through the axle. This first motion shaft carries the usual face wheel, which is made of cast iron, about 12 ft. in diameter (the rim of which forms the bearing surface for the brake), and gears into a main pinion or "wallower" about 4 ft. in diameter, fixed on the top of the upright shaft. This shaft carries at its lower end a spur wheel, about 14 ft. in diameter, which drives the spindles of six pairs of millstones which are posited around it, each pair being fitted with a "lift tenter."

In order to maintain the efficiency of windmills, it is of much importance that the wood and iron work should be of the best description; the main axle should be of wrought iron, having a cast-iron flange of large diameter keyed on its front, and furnished with recesses for receiving the arms of the wings. The brake-wheel should be strongly constructed, and covered with hard wood, and of ample breadth, as well as that of the friction strap, which should be strongly secured to the framing at the top of the tower; and it would be an improvement to have a small force pump worked from the top of the upright shaft to discharge water upon the break-wheel, when the mill requires to be arrested in a gale of wind.—*Practical Mechanics' Journal.*

The Liverpool Shipowners' Association, at a meeting held on Saturday, adopted a report which recognised the necessity of an early revision and readjustment of the dues levied upon vessels using the graving and other docks of the port. Amongst other things, the Association recommended that the charges for the graving docks in all instances should be regulated by the length of the vessels and the time of occupation. With respect to the wet docks it was recommended that at the time of every vessel—whether steam or sailing—entering she should pay tonnage dues on her gross tonnage, which should entitle her to remain in the dock for a fixed period, and that in addition every vessel should pay for the quay space occupied in discharging or loading her cargo according to the extent of space and time of occupation.

MUSGRAVE'S IMPROVEMENTS IN STEAM BOILERS.

FIG. 1

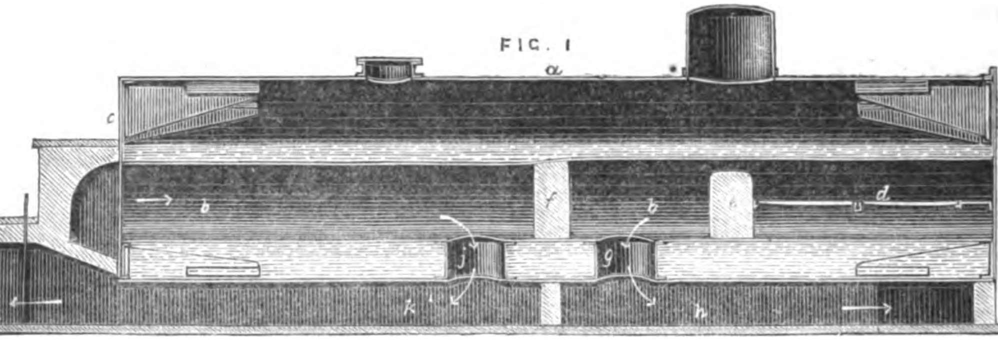


FIG. 2

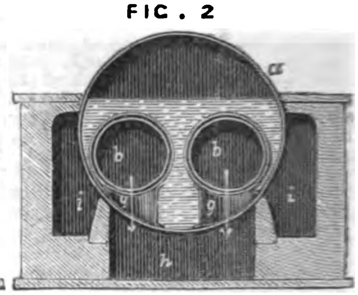

MUSGRAVE'S IMPROVEMENTS IN STEAM BOILERS.

THIS invention, patented by J. Musgrave, engineer, Bolton, is applicable to steam boilers having two longitudinal flues containing at one end the fire grates; these flues extend from one end of the boiler to the other and impart the requisite strength to the ends but they are closed near the bridge at the firing end either by partitions of fire-brick or otherwise. The products of combustion descend through vertical flues into an external horizontal flue; they then pass along external flues to the end of the boiler, where they enter the end of the internal flues, from whence they descend through vertical flues into an external flue which is in communication with the chimney.

FIG. 3

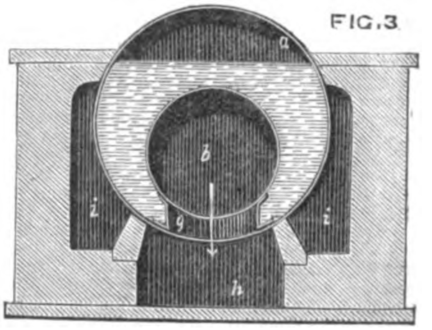

Fig. 1 is a longitudinal section of the improved boiler; fig. 2 is a transverse section through the firing flues of the same.

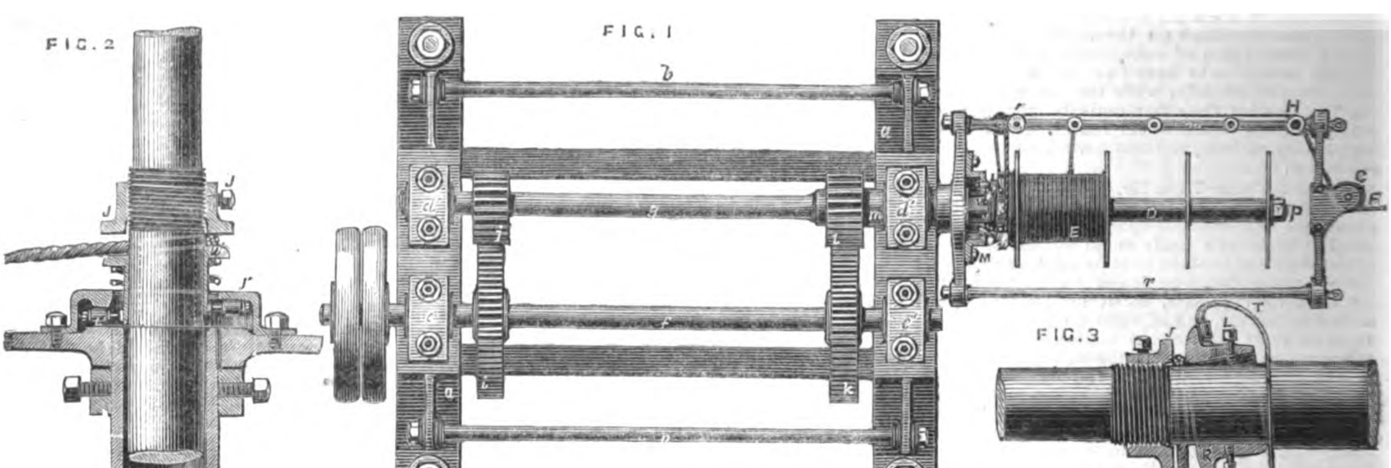
a is the outer cylindrical casing of the boiler; *b*, *b*, the two internal flues extending from one end of the boiler to the other, thus imparting the requisite strength to the ends *c*, *c*. The flues *b* are rather larger at the firing end than at the other, to give space for the grates *d*, *d*, and bridges *e*, *e*. The flues *b* are closed at about the centre of their length by the partitions *f*, made by preference, of fire-bricks. The products of combustion, passing over the bridges *e*, pass through the vertical flues *g* into the external longitudinal flue *h*, which conveys them towards the firing end of the boiler, where the longitudinal flue *h* branches upwards and conveys the products of combustion into the side flues *i*, which extend the whole length of the boiler, and deliver them into the ends of the internal flues *b*, from which they descend through the vertical flues *j* into another external flue *k*, which is in connection with the chimney.

Fig. 3 shows an end view of a boiler constructed according to a modification of this invention. In this view the boiler is made with a single flue *b* containing the fire grate and bridge. The products of combustion, after passing over the bridge, descend through the vertical flue *g* to the horizontal external flue *h*, then into the side flues *i*, from whence they return into the internal flue *b*, and again descend through the vertical flue *j* to the external flue *k*, which communicates with the chimney.

In boilers of the ordinary construction with internal flues, it is well known that the expansion is very unequal, particularly when the steam is being raised rapidly on starting; this unequal expansion is due to the upper surface of the flues, and the upper portion of the cylindrical shell of the boiler, being heated before the lower parts; but in the boiler above described such unequal expansion cannot take place, as the upper and lower parts of the boiler, both internally and externally, are heated equally at the same time, thus establishing a complete circulation of the water in the boiler as soon as the fires are ignited.

BROOMAN'S IMPROVEMENTS IN THE MANUFACTURE OF ROPES, CORDS, CABLES, &c.

FIG. 2 FIG. 1 FIG. 3



BROOMAN'S IMPROVEMENTS IN THE MANUFACTURE OF ROPES, CORDS, CABLES, &c.

THIS invention, patented by Mr. R. A. Brooman, Fleet-street, is based upon the proportional resistance of the strands composing the cord, rope, or cable, according to their thickness or torsion—that is to say, that if in a rope composed of four or five strands, and manufactured according to the ordinary method, there be one or several of different thickness and of unequal torsion, the strain borne by the entire rope being equally spread over each strand, the weakest will break first, consequent upon its want of resistance comparatively with the others. Each strand will thus break successively, as the resistance offered by the entire rope is no longer sufficient to resist the strain exerted upon it.

By the method of manufacture which forms the subject of this invention, the whole strain is, on the contrary, spread proportionally over each strand according to its thickness and torsion. The result is, that the rope is capable of exerting its maximum tension without breaking.

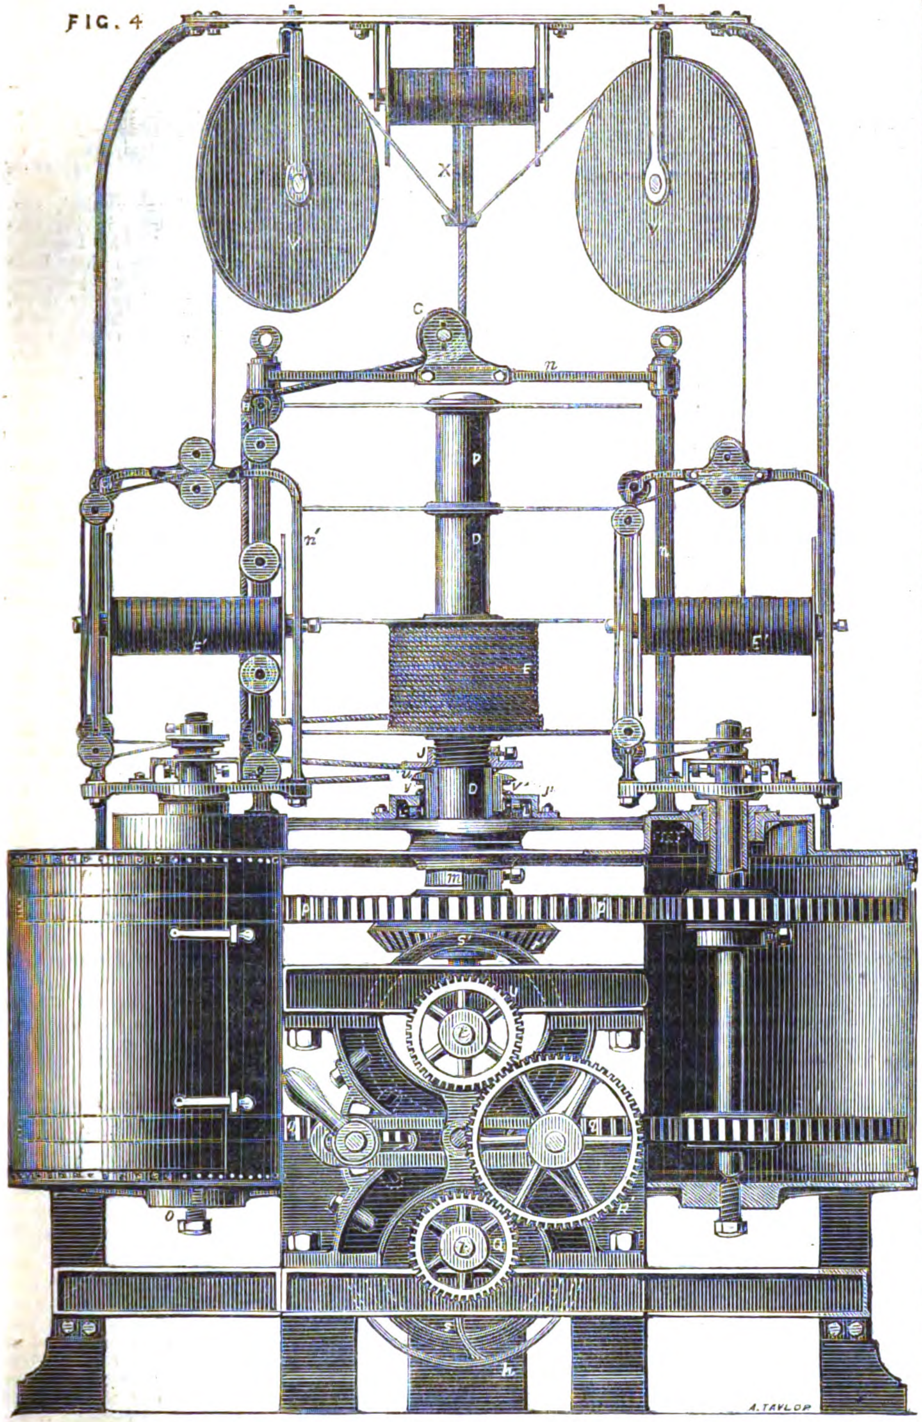
The manufacture, according to the present invention, is divided into three distinct operations—viz., spinning, winding or warping, and twisting. These three operations are performed in two machines—viz., a spinning machine, which performs also the winding and warping; and a twisting machine. These two machines will be well understood on reference to the accompanying engravings.

Fig. 1 is a plan of the spinning machine; fig. 4 is a sectional elevation of the twisting machine, taken at the top of the mechanism for driving the flyers; figs. 2 and 3 are details on a larger scale of the different arrangements applied to the flyers for nipping.

First Operation, Spinning Machine.—This machine is mounted on frames *a*, *a*, of cast iron, wood, or other material, united by cross bars *b*. On the frames *a* bearings are fixed, in which shafts *f*, *g*, are free to revolve. The main shaft carries two pulleys, one of which is loose; inside the frame

BROOMAN'S IMPROVEMENTS IN THE MANUFACTURE OF ROPES AND CORDAGE.

FIG. 4



is a toothed wheel i, which gears into a pinion j, fixed on the shaft g of the spindle D. A second toothed wheel, fixed on the shaft f, gears into a pinion l on the socket of the flyer n. The pinion j which drives the spindle D and the pinion which drives the flyer being of different diameters proportional to the wheels, the wheels turn in the same direction, but at different speeds. The object of this arrangement is to impart at the same time a twist to the strand and to wind it upon the bobbin E, as will be explained in the description of the flyer and its operation. The hemp for forming the strand is kept stretched at F, and becomes twisted by the flyer, which makes 500 revolutions a minute. The strand then passes under a grooved roller G, then over another grooved roller H and a third grooved roller I. On leaving the roller I the strand is nipped between a grooved cap J and a hinged nipper on the socket K. The nipper carries two rods L, to which rollers are attached abutting interiorly against an eccentric ring M fixed on the rail of the flyer. Springs pressing upon the nippers cause them to press against the cap J. The cap J is threaded as represented in figs. 2 and 3, in order that its position may be regulated according to the thickness of the of the strand. The flyer in revolving carries with it the eccentric ring M, which by pressing upon one or other of the rollers L opens first the nipper u, then the nipper u^1. The strand is in turn seized by one of these nippers, and released by the other as the flyer and spindle revolve; it thus receives sufficient tension to allow of its passing over a pulley N, and over one of the rollers o, o, o, which facilitates its winding on one of the compartments of the bobbin or drum E. When the bobbin E is full, it is removed by unscrewing the bolt P, and an empty one is substituted for it. The nipping apparatus may be varied, as shown. In the apparatus shown at figs. 2 and 3, the nippers u, u^1, have substituted for them slides carrying rollers L^1, L^1, which pass under the cam J_1, and the nippers of each slide are pressed upon by springs, as already explained. Or a socket R (see fig. 3), widened at the bottom, may be made to oscillate round the spindle S. This socket is kept pressed against the grooved cap J by the roller L^2 fixed on the end of a strong spring T. Or the spring may be placed under the cam or eccentric ring; but in that case, the eccentric would push the lever or nipper from above, instead of acting from below as before. The object of these different arrangements is to retain the cord at a given moment nipped between the cap J and the appliance for pressing, in order to obtain the necessary tension.

Second Operation, Warping.—The warping of the spun strand is effected in a machine precisely similar to that above described, but of larger proportions. The bobbin carrying the spun strand is placed on the spindle of the machine, which imparts to it a regular torsion before being submitted to the twisting machine.

Third Operation, Twisting.—This machine consists of a circular or polygonal frame Fig. 4, A, supported on four or six cast-iron feet. The circumference is divided into four parts, on each of which is a drum B, of sheet iron fixed to the frame A by rivets, or by any other mode of attachment. The two bottoms of the drums are formed by plates o, cast with the frame and strengthened by ribs. In the centre of the frame is a vertical shaft p supported by bearings and collars; it is prolonged above the frame and forms the spindle D, or rather the axis of the drum E. On the shaft p, a large toothed wheel q is fixed concentric with the bevel wheel r, which receives motion from another bevel wheel s on a horizontal shaft t, on which the driving pulleys h, h^1, are fixed. Outside the frame, and on the same shaft t, there is a toothed wheel Q, which, through the wheel R^1, actuates the wheel U on a horizontal shaft t_1. This shaft is similar to the shaft t, with the exception of the driving pulleys; it carries a bevel wheel s_1 in gear with the bevel wheel r^1, in a piece with a large toothed wheel p^1 on the socket m of the flyer n. Four small flyers are arranged round the central spindle to receive the spun and warped strands. The flyers and spindles are arranged, as has been already mentioned, for the spinning and warping machine, and carry drums or bobbins E^1 placed horizontally, from which all the strands for forming the rope or cable proceed. Each strand on leaving the flyer n^1 is subjected to torsion, and passes over a large pulley V, and then through a guide or "twizzle." On leaving the twizzle the strands become united in one, either by themselves alone or round a central core X, as seen in fig. 2. When the rope or cable is being formed—that is to say, when the large central flyer n and the drum E work—each of the strands, according to its torsion or size, becomes more or less elongated, the thickest becomes first placed on the core, if there is one, then the strand next larger, and so on for all the strands; this is supposing there be inequality in the strands. Thus a rope or cable is formed, all the parts of which are equally distributed in proportion to the resistance they are capable of presenting. When all the strands are equal in diameter and torsion, they become twisted together and form a strong and even cable. The rope becomes twisted and wound upon the drum on the main spindle in a similar manner to the winding of the strands upon the bobbins, as before explained. The twisting machine may be arranged horizontally—that is to say, the three or four spindles which carry the strands may be placed at a distance of, say, six or seven feet from the twisting spindle which is in the front—and may be worked by a driving shaft or by pulleys. The chief object of the large pulleys is to facilitate the passage of the twist of the strand, which, when it has once entered the groove of the pulley, cannot be again diverted until it arrives at the twisting spindle; this is an essential feature in this invention.

EXPERIMENTS AT SHOEBURYNESS.

An important series of experiments was made on Tuesday at the practice ground of Shoeburyness, in presence of an unusually large assemblage of naval and military officers, and other scientific persons interested in the subject of artillery and iron-plated ships, besides the members of the Iron-plate Committee and the Ordnance Select Committee, under whose especial direction the experiments were made. The presence of his Royal Highness the Prince of Prussia added to the interest of the occasion, and his Royal Highness appeared to take great interest in witnessing the effects of heavy guns against one of the strongest iron targets that has ever been experimented upon. This target, like those which have been tried before, was to represent a section of the side of an iron ship-of-war, stronger it is supposed than either the "Warrior" or the "Minotaur," a ship which is already named the "Bellerophon," although she is not yet commenced, and is designed by Mr. Reed, the present Constructor of the Navy, to surpass all that has yet been done in building iron-plated ships of war. This target is called, therefore, the "Bellerophon" target, and it has been constructed at the Millwall Ironworks, by order of the Lords of the Admiralty.

The following is a description of the target:— It was 20 ft. 9 in. long, by 8 ft. 6 in. high, composed of rolled armour plates 6 in. thick, backed by 10 in. of teak, and two ⅝-inch plates for skin. Two external longitudinal stringers are wrought behind each armour plate through the whole length of the target. The two behind the lower plate are formed of angle iron 10 by 3½ by ½, and those behind the upper plate of angle iron 9½ by 3½ by ½. Frames 2 ft. apart. The bolts in the lower plate are 2¾ in. diameter, and those in the upper 2½ in., and have conical heads. The 2¾-in. bolts are double nutted, and the 2½-in. single nutted.

It was generally considered by those who had seen the other targets that this was a most excellently made one, and of very great strength. It will be remembered that the target fired at in March last had three plates of different thicknesses, 5½ in., 7½ in., and 6½ in., with 9-in. teak backing, and an iron skin of 2 in. thick.

It was arranged by the Ordnance Committee that the upper plate was to be tried by 68-pounders, or, strictly speaking, with cast iron shot weighing 66½ lbs., and the Armstrong 110-pounder service gun, with shot of the same weight, and the same charge of powder. The range was fixed for all the rounds throughout the day at 200 yds., which was the same as that taken against the "Minotaur" target. The first round with the 68-pounder produced the usual dent of about 2¼ in. into the plate. The second round was the Armstrong 110-pounder, with 66½ lb. solid and conical headed shot; this made a very similar dent to that of the 68-pounder.

The third round was a salvo of two 68-pounders and three Armstrong 110-pounders, with the same weight of shot and the same charge of powder as the 68 pounder. This terrific attack the target bore without much evidence of injury, though it is true the one Armstrong missed fire and one hit the very top edge of the target, breaking the angle iron behind. The other shots merely indented the plate.

The lower plate was now to be fired at by the heavy Armstrong guns of the service, and by the Whitworth shell, with an entirely new gun expressly made by order of the Ordnance Select Committee, a muzzle-loading gun which has for some time past been mentioned as a gun intended to serve as a broadside gun for the Navy.

The first round fired at the lower plate was intended to have been one from the ordinary 68-pounder, but the effect of these shots being so well known, this shot did not come off, and in its place was fired the Armstrong 110-pounder, with 16 lbs. of powder and a hardened steel shot. The effect of this was to make an indentation and start a bolt, a result much less than was expected. The second round was from the smaller Whitworth gun of 5¼ in. calibre, with shell of 70 lbs. weight and 2 lb. 6 oz. bursting charge, and 12 lbs. charge. The shell, which is of steel, and flat-headed, struck about a foot below the upper edge of the lower plate, penetrating about 1½ in., and starting a bolt. The third round was from the new gun described as a 7·1-inch calibre, 16 lbs. charge, steel shell 117 lbs., with a bursting charge of 2 lbs. To the astonishment of every one, and most of all the Ordnance Select Committee, this gun produced very little effect upon the target—not much more, as it was remarked, than if a Dutch cheese had been fired at it from a cross-bow. The next round set down in the programme was for the 7-inch Whitworth gun, the same gun that sent the shell at 800 yds. through the "Warrior" target in November, 1862, and which was made at the Royal Gun Foundry. The shell fired from this gun weighs 151 lbs., and contains a bursting charge of 5 lbs., the charge being 27 lbs. The first shell fired from this gun burst at a short distance from the gun, and as there was no other shell prepared and ready, some delay arose, and it was necessary to proceed with the firing of the larger Armstrong guns while another shell was being prepared. We learnt that there were no flannel bags ready for holding the bursting charge, and as this is indispensable to the proper action of the Whitworth shell, it was necessary to extemporize one, and this was fortunately done under the instructions of Mr. Whitworth himself, who was present, otherwise the men were about to fill the shell with loose powder, in the way that the old shell is filled —a blunder that would have effectually prevented nearly all the power of the shell from being exerted. The shell was, however, ready before it grew dark, and was the last shot fired.

The 10-in. Armstrong smooth-bore gun, muzzle loader, was now fired with a 150-lb. spherical shot of cast iron, with a charge of 35 lbs. The shot missed the lower plate, and struck the upper one about 3 ft. 6 in. from the mark, indenting it and starting a bolt.

The same gun was now charged with a steel spherical shot of 150 lbs., with 35 lbs. of powder; the effect of this was to strike the plates at the part where they joined. The shot buried itself just below the face of the plate, and therefore went through it and into the wood. One frame was broken, and the skin was bulged and slightly cracked. The next round was from the 300-pounder Armstrong, 10-in. calibre, 35 lbs. charge, and a solid cast-iron shot. It struck fair on the upper plate, however, produced very slight penetration with some few cracks in the direction of the dents made by the 68 and 110-pounders, and it broke a rib behind the target. The velocity of this shot was 1,150 ft. per second, and that with the 150-lb. shot was 1,500 ft. per second at the time of impact, showing the great importance of velocity for penetration.

The last round fired was with the Whitworth shell from the 7-in. gun. This penetrated quite through the plate, bursting in the timber backing and bulging the skin, opening out the plates at a junction where they were rivetted about an inch and a half. This result, therefore, tended to confirm the previous reputation of the Whitworth shell, as it was the increased thickness of the plates by very nearly two inches which only prevented the shell getting into the ship as it did in the "Warrior" target. It would appear that it is only necessary, therefore, to increase the calibre of the shell and the gun to penetrate the "Bellerophon" as easily as the "Warrior." It should be noticed of these experiments, as in the trial against the "Minotaur" target, that the Whitworth shell, with a charge of nearly 10 lbs. less powder and a gun of 3 in. less calibre than the heavy Armstrong, proves to be a more effective weapon against iron plates.

The target on this occasion certainly came off victorious; and though the Committee's great gun was "nowhere," the Admiralty may feel some confidence in laying down the "Bellerophon."—*Daily News.*

THE LIGHT DRAUGHT MONITOR "YAZOO."

One of the twenty light draft monitors ordered in March last by the Government, is fast approaching completion at the extensive shipyard of Wm. Cramp and Sons, Kensington, Philadelphia. The "Yazoo" will be 225 ft. in length over armour, breadth of beam 45 ft., and a total depth amidships of 9 ft. 1 in. The vessel will have a flat bottom, with 1 in. dead rise, the bilge to be formed by a radius of 15 in.

The sides of the inner hull are vertical, surrounding which is another iron hull, having also vertical sides, the depth of which is 3 in. less than that of the inner. The space between these hulls is arranged so as to be filled with water at pleasure, for the purpose of giving the vessel greater draft, and bringing the deck near the surface when in action. The interior of the vessel is divided into compartments by water-tight bulk-heads of plate iron, communication between them being afforded by wrought-iron water-tight doors. The water compartments will be filled and emptied by two powerful pumps, each capable of delivering three thousand gallons per minute.

For propelling the vessel, two engines, working entirely independent of each other, are to be used. The cylinders of each will be 22 in. diameter, and 30 in. stroke of piston. These are to be connected with two propellers of cast iron, each 9 ft. in diameter and 12 ft. pitch. The surface condenser will have 3,294 in., with a cooling surface of 2,500 square feet. There are to be two horizontal tubular boilers, each to have four furnaces, with a grate surface of 150 square feet, and a fire surface of 4,120 ft.

There are also to be two circulating pumps, with a double oscillating engine for driving them. The draft of water for this vessel when loaded, will be 6½ ft.; area of water line, 7,140 square feet; displacement at water line, per inch of draft, 17 2-10 tons; and total displacement, at 6½ ft. draft, 1,175 tons. The work on this monitor is of a superior character, and will again add to to the reputation of her builders. The plating and backing of wood, size of turrets, construction of deck and interior, being the same as the old monitors, a description is rendered unnecessary.—*New York Army and Navy Journal.*

PROGRESS OF A YORKSHIRE SMELTING TOWN.

Twenty years ago, says a correspondent, Cleveland enjoyed all the quiet stagnation of agricultural life. Since then a rapidly increasing tide of progress has set in. Then there was only one railway with an arm extending about three miles into the district to Middlesborough Docks. Now our railways, without reckoning innumerable sidings, branches to mines, and to private works, are at the least 67 miles in length, and managed by three companies. Then Eston was a hamlet with the most meagre population, now it numbers 5,000 souls. Middlesborough from 7,000 has sprung to nearly 25,000. South Stockton from other parts of the kingdom has drawn in a population of 7,000. The new towns and villages of Saltburn-by-the-Sea, Eston Junction, New Rosedale, and South Bank have sprung up, and the old places have experienced almost a resurrection. Iron mines employing thousands of hands have been opened at Eston, Upsil, Hutton, Low Cross, Ingleby, Upleatham, Staithes, Swainby, Hinderwell, and other places, and from these hundreds of thousands of tons of iron-stone are annually extracted. When the Cleveland ore was first opened out at Skinningrove and a cargo brought to the Tees, one of our present leading firms rejected it as being little better than quarry rubbish. Circumstances, however, led them to alter their decision, and the oolitic beds of Cleveland have exerted, and are yearly exerting, more and more influence upon the iron trade of this country, whether in iron ships, iron rails and bars, mechanical combinations of iron, or crude pigs for export or for home manufacturing purposes. Just now nearly a score of new furnaces are being built in the district, involving great outlay of capital, and several new iron ship yards are projected. New railways are in progress, and new mines are about to be opened at Skelton, Skinningrove, Hunteliff, and other places. On the part of the Established Church, new churches, mission rooms, and schools have been and are being built; and the Nonconformists, never last in the field, have dotted the new towns with religious structures, many of them of large dimensions.

THE INDIAN TELEGRAPH.

Colonel Stewart, Sir Charles Bright, Captain Stewart, Mr. J. C. Laws, and Mr. F. C. Webb have arrived at Malta in the steamship "Valetta," from Marseilles, and passed on in the same vessel for Alexandria, for the purpose of superintending the laying of the electric cable in the Persian Gulf. The five ships forming the squadron for conveying the cable to its destination will rendezvous at Bombay, whence they will proceed to lay their respective sections. The submergence of the cable is to commence as soon as possible after their arrival. The staff of electricians, telegraphists, &c., have been sent in the various cable ships, all of which have left England, and the early ones must now be near Bombay. The submarine line will be laid in four sections between Bussorah, at the head of the Persian Gulf, and Kurrachee, having intermediate stations at Bushire, Khasab, and Gwadel. The land line from Bussorah to Bagdad, and thence through Asia Minor, is being proceeded with with all possible despatch. The persons connected with the undertaking who passed through Malta said that they expected to have the line in working order within six or seven months from the present time.

ON MAGNETO-ELECTRICITY, AND ITS APPLICATION TO LIGHTHOUSE PURPOSES.*

By F. H. Holmes, Esq.

As this is a Paper on the Application of Magneto-Electricity to Lighthouses, I will begin by saying a few words on lighthouses themselves, their former and present state, and the systems now generally followed in the arrangements for lighting.

Formerly, lighthouses were very few, and were nearly all coal fires on high cliffs or towers, and most of them were the property of private individuals; but, as shipping increased, so the lighthouse system became more and more developed, both in the number of lighthouses and in the improvement of those already existing. The coal fire gradually gave way to the oil lamp and candles; next we find the introduction of spherical mirrors or reflectors; and these, again, were superseded by parabolic reflectors, sometimes to the number of more than thirty in one lantern. After this came the introduction of the "Fresnel Lens," which took the place of the reflectors and their lamps, however numerous they might be, and required instead one central lamp.

This "Fresnel Lens" has again grown, so to speak, larger and larger, as the want of a more powerful light was felt, till it has now a diameter of 6 ft. and a height of 10 ft., for to increase the quantity of light the size of the lamp must be increased, and the lens in proportion, or it would have been so far out of focus that the intention of the lens would have been frustrated.

To make these progressive improvements in lighthouses vast sums of money had to be expended; and now let us see what was the end sought:—First, to improve the light itself. This is done by the substitution of a lamp of four concentric wicks (the largest nearly 4 in. in diameter) for the coal fire. If the improvement had stopped at that, it would have been small indeed, but this lamp is more under command than the coal fire. The value of the introduction of oil is not so much then, on account of its greater power as for its aptitude for the employment of economizing apparatus, whether this consists of reflectors or lenses. All incandescent bodies give out rays as it were from the centre to the circumference of a sphere; of such rays, only those which fall on the sea would be useful to the mariner; but by means of reflectors those rays which would pass inland, or upwards, or downwards, are reflected towards any required point, and by a proper arrangement of a series of reflectors, the whole or nearly the whole of the rays, are directed where required. The Fresnel lens consists of a middle refracting belt, and a double series of reflecting prisms, or zones, as they are generally termed, and, when properly constructed, it has the property of collecting all the rays into one horizontal beam, so that all the light from the lamp is utilized. Thus, then, we see great strides have been made since the introduction of oil lamps, as regards the lenticular apparatus—in fact, that may be said to be nearly perfect; let us then return to the consideration of the light itself for a moment.

Whether a large or small lamp be employed it will make no difference in misty weather, so long as the thickness of the flame is the same, for a large lamp may be equal to ten or twelve smaller ones, and, if replaced by these ten smaller, it will be evident that when one of these is obscured by mist the whole of them will be obscured. Quantity of light, then, will not add to its power of penetrating mist. By making the large lamp with four concentic wicks, the intensity of the light is a little increased, and such a lamp will penetrate further through mist in a slight degree. But it is in misty and hazy weather that the light is most required; hence, now that everything is nearly perfect in a lighthouse, the authorities, both in this county and elsewhere, are directing their attention to the only thing wanting to make the whole system perfect, that is, a light capable of penetrating mist; and as this power depends on the intensity of the light, and electricity is capable of producing the most intense light known, it was naturally looked to as the possible means of perfecting the whole system. But the light produced by electricity, to be applicable for lighthouses, must be certain and constant, not liable to extinctions or any great variations, as the first would tend to endanger vessels seeking and not finding the light; and if a fixed light had much variation, it might be mistaken for a revolving light.

Let us now see whether electricity can produce a constant steady or uniform light. Frictional electricity will give a succession of flashes intensely vivid, and might be used for the purpose, but for the fact that the slightest moisture is sufficient to convey the whole charge to the earth. The various forms of galvanic battery are all capable of producing a steady and intense light; but still (besides the great expense) they are not applicable, because of the necessarily varying current, which becomes weaker and weaker as the solution becomes saturated. The magneto-electric machine is then the source from which one would naturally expect a light which should be invariable in its nature, and capable of being continuous for any given time, as the current produced by this machine is constant as long as the helices revolve with the same speed, and the speed can be easily regulated to any required velocity.

The electricity derived from a magneto-machine is induced in coils of wire, by the changing of the magnetic polarity of pieces of soft iron inclosed within the coils or helices; and the quantity or intensity of the induced current depends, first, on the amount of magnetism induced in the soft iron; secondly, on the facility with which the poles of the magnetized soft iron can be reversed; thirdly, on the velocity with which the change of polarity takes place; fourthly, on the length and diameter of the wire forming the helices.

The amount of magnetism induced in the soft iron depends on the size and force of the steel magnets employed, and on the weight and softness of the iron in the helices; but the weight in practice of the soft iron is limited by the weight of the steel magnets, for, if too heavy, the steel magnets will be slowly deprived of their magnetism. To facilitate the change of the poles the soft iron cores of the helices are not solid pieces of iron, but are tubes, single, double, or treble, as it is found by experiment that the same weight of iron, when divided in this manner, loses or takes magnetism in much less time than when in a solid form.

There is a limit to the velocity to be employed when the maximum of electricity is required, for this reason. It has been already remarked that the amount of electricity depends on the amount of magnetism taken up, and that the soft iron takes time to become saturated, as it may be termed, with magnetism; hence, if the velocity be too great with which the cores move from one pole of a magnet to another, there will not be sufficient time for the cores to become saturated. But as again the quantity of electicity increases as the velocity increases, it is necessary to ascertain this maximum point exactly, which is easily done, either by experiment or calculation, based on certain data. The length and diameter of the wire require to be different, according to the current required; for a short thick wire forming the helices represents a galvanic battery composed of a dozen, say, of very large pairs of plates, whilst a long, thin wire would represent a battery composed of thousands of small plates. In other words, supposing the size of the helices to remain the same, if they are composed of thick short wires, quantity is obtained; but if composed of long thin wires, intensity will be the result.

From all this it results that there are certain laws known and established, by which a magneto-electric machine can be made to give a current of any given amount of electricity, with any given ratio between its quantity and intensity.

Having seen on what the production of the current depends, the next point to observe is, the peculiar nature of this induced current. It differs essentially from a galvanic current in this, that while the helices are revolving, the direction of the current is reversed as the core of soft iron passes each consecutive pole of the steel magnets.

It now remains to explain how the current generated in the wires of the helices is to be withdrawn from the machine. In the first place, all the helices are connected in two, or four, or more series; and in doing this great care must be observed that the direction of the coil of every alternate helix is in an opposite direction—that is, if one is wound as a right-hand screw, the next should be as a left-hand screw, or, what amounts to the same thing, supposing all wound in the same direction, then the two inner ends of the wires must be joined of, say, numbers one and two, and the two outer ends of the wires of number two and three, and so on through the series; and lastly, the terminals of the series might be soldered into two insulated discs, and then led from the machine by two pieces of metal kept in contact with the outer surfaces of these discs by a slight spring; such an arrangement allows the alternating current to pass from the machine, and such a current will produce a light, but this light has certain disadvantages. It is never white, but always more or less blue or brownish—in fact, it is like the electric light obscured by placing it behind a flame from spirits of wine. It is also extremely injurious to the eyes, both from its colour and tremulousness; I therefore do not use this current, but in its stead I convert this constantly-inverting current into two that flow from the machine in one direction only. This is accomplished thus:—One half of the helices are arranged so as to arrive on the poles of the magnet at the instant that the other half are exactly midway between the poles. Thus there are two distinct currents; and what may be called the dead point—that is, the point when the current inverts in one series—occurs exactly at the time when the other current is at its maximum; so that if now the inverted currents can be again inverted in both of these distinct currents, and that the two now flowing in one direction can be united as one compound current, it is evident that the result will be a current nearly as uniform as that from a galvanic battery, with the advantage of equable continuity. This is done by the two commutators, which consist each of two insulated rings of metal, of such a form at the periphery that two rollers or rubbers change sides from one disc to the other at the same instant that the current is reversed. Then, by combining the two commutators, a compound current is obtained that will produce a constant white light or perform any of the other functions of the galvanic current, and in a more perfect manner, as it is more uniform in its action.

A steady and constant current thus obtained from the magneto-electric machine, is only one part of the problem of producing a constant and steady light; and although the most important part, still it would be perfectly useless without an efficient lamp or regulator. In order to understand this, it is necessary to explain that the carbon points used for producing the light, or for converting a portion of the electric current into light, are consumed, and that the rate of consumption is irregular, owing to the irregularities in the structure of the substance used, which is the kind of graphite deposited in the gas retorts, sawed up into pencils about a quarter of an inch square; but, as the consumption is irregular, no clockwork, with continuous motion, could be employed for the purpose of causing the carbons to approach as consumed, for it must be understood that the steadiness of the light, as well as its brilliancy, depend on the two carbon points being maintained constantly at a certain distance, corresponding to the strength of the electric current.

Many pieces of apparatus, more or less complicated, have been invented from time to time for the purpose of regulating the movements of the carbon electrodes, and many of them I have tried; but none of them, as formerly constructed, could be used in a lighthouse, because they were more or less uncertain in their action, and because the clockwork was too delicate and liable to accident in other hands than those of an electrician. The question, What constitutes a good regulator? must be answered by stating what it must accomplish; and, moreover, it must perform its several functions in the most simple manner. It must, in the first place, maintain the carbons at a given distance, whatever be the variation in the state of consumption, and must also be capable of being adjusted to

* Read before the Society of Arts, on the evening of Wednesday, December 2.

any strength of current; secondly, if by any accident the current should be interrupted, and the light thereby extinguished, the regulator should be capable of relighting at once with full brilliancy—that is, not only must it allow the carbon points to touch to re-establish the current, but must separate them again instantly, or there would be no light. Such a regulator we have here, for its construction is simple, and it performs its different functions in a most perfect manner. Its construction is this:—The upper carbon is attached by a kind of small vice to a bracket, standing out from a tube, which slides freely in a column. The lower carbon is fixed in the end of another tube, exactly under the other carbon. Both of these tubes are put in motion thus: Two cords, passing over pulleys, properly arranged, are wound on one spindle, but in opposite directions. On turning a stud fixed on the end of the spindle, the regulator is wound up—that is, the top bracket is raised, and the lower tube depressed. On removing the hand from the stud, the upper tube would descend, and, being loaded, would cause the lower tube to rise; but to prevent this, while the regulator is out of use, a bolt is pushed in, which prevents any movement in the regulator till it is again withdrawn. The regulator being wound up, the carbons are firmly fixed in their places by tightening the holders, and are then adjusted so as to bring the points in the focal plane by turning a spindle, to which the fixed end of the cord belonging to the lower carbon is attached. So far, the regulator is only a means by which the carbons can mutually approach each other with a certain relative speed, depending on the different diameters of the two parts of the spindle around which the cords are wound. But if the carbon points remain in contact, there will be no light. Some contrivance, then, was necessary to separate the points to the distance, which, by experience, is found to give most light, and to maintain that distance between the points constantly, till the whole of the pair of carbons is consumed. These two operations are accomplished thus:—The fixed end of the cord which works the upper carbon is attached to one end of a lever; the other end of the lever has a piece of soft iron attached to it, over an electric magnet, so that when the bolt is withdrawn, and the carbons run together until they touch (thus allowing the current to pass), this electro-magnet instantly, by the action of the same current, lifts the cord, and with it the upper carbon, to the required distance. But this is not all; for the carbons would again run together, were there not some contrivance to prevent them. To accomplish this, advantage is taken of these two facts—first, that the quantity of electricity is proportional inversely to the distance between the carbon points; secondly, that the strength of an electro-magnet is proportional to the quantity of electricity passing through the wire that surrounds it. Bearing these two facts in mind, it will be easy to understand the use of the second electro-magnet. Over this electro-magnet, at a small distance above it, is placed a lever, one end of which is drawn down by a spring, the strength of which can be regulated by a thumb-screw. The fulcrum is between this end and the centre. The other end of the lever is furnished with a catch, and immediately over the electro-magnet a piece of soft iron is fixed in the lever. On the carbons being allowed to touch as before, not only are they separated by the means described, but this second lever, acted on by its electro-magnet at the same instant, is drawn down towards it, and thus brings the catch between the teeth of a wheel placed under it for the purpose, and effectually locks the regulator. The strength of the spring is now adjusted till its tendency to lift the catch out exactly balances the current which draws it down. Should the distance now increase but the one-two-hundredth of an inch, the spring will be stronger than the current, will lift the catch, and the carbons will approach; but by doing so more current passes, the electro-magnet is strengthened, and is again enabled to overcome the spring and draw down the catch, and thus by their mutual action the distance between the carbon points is all but invariable.

When these regulators are employed in a lighthouse there are a pair for each lens and two small lenses, so that although it may take ten minutes to replace the consumed carbons, still the light is never extinguished; for, suppose the carbons consumed in the lens No. 1, the regulator is ready in lens No. 2; and all the light-keeper has to do is to bolt the No. 1 regulator and draw the bolt of the regulator in No. 2 lens; the current is thus diverted, No. 2 is instantly lighted, and the lighting of this extinguish[illegible] No. 1.

(To be continued.)

TO CORRESPONDENTS.

The Mechanics' Magazine is sent post-free to subscribers of £1 1s. 8d. yearly, or 10s. 10d. half-yearly, payable in advance. Post-office orders made payable to Mr R. A. Brooman, of 166, Fleet-street, E.C.

Advertisements are inserted in the Mechanics' Magazine at the rate of 6d. per line, or 5½d. per line for 6 insertions, 5d. per line for 13 insertions, 4½d. for 26 insertions, and 4d. a line for 52 insertions. Each line consists of about 10 words. Woodcuts are charged at the same rate as type. Special arrangements made for large advertisements.

All communications should be addressed to the Editor, 166, Fleet-street.

To insure insertion in the following number, advertisements should reach the office not later than 5 o'clock on Thursday evening.

Received.—J. N.—J. W.—J. H. T.—T. M.—W. W.—J. R.—G. R.—J. M. G.—W. L.—C. H.—Captain B.

S. P.—If the kind of turbine to which you refer, or indeed any other, is locked fast, so that it cannot revolve, the water will pass through it, just as it will overflow the buckets of an overshot water-wheel under similar circumstances; but it will exert a force or pressure on the vanes, tending to put them in motion. We must refer you to our advertising columns for the further information which you require, as we know nothing accurately of the very small turbines of which you speak.

George Beake (St. Leonards).—Your invention might be found useful under certain circumstances.

T. S. (Wolverhampton).—Apply to the Board of Trade. The protection is similar to that given by a patent—that is to say, it enables you to prosecute any one employing the same device for an infringement of your rights—that is all. As to the cost, we cannot give you accurate information—we believe the sum is about £5.

J. Monteih (Dalkeith).—You certainly labour under a singular error. Although an account, as you state, of a new material for tanning has appeared in our paper, there is no earthly reason that we should sell it, or be able to afford you any information as to its price in consequence.

Correspondence.

NARROW GAUGE LOCOMOTIVES.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

Sir,—I have read in your publication of the 27th November, an account of a narrow-guage locomotive engine, made by Mr. G. England, of Hatcham Iron Works, New Cross, for the Festiniog Railway Company, now working upon their railway between Festiniog and Port Madoc; and as I happen to know something of the history of those engines, I beg to correct an important error in one part of the leading feature of your article upon that subject.

There, it is stated, that the invariable answer of several engineers of eminence, who were consulted from time to time as to the possibility of employing locomotive power on so narrow a guage as 2 ft., was, that it was impossible. This, I am aware, is correct; but the portion that I consider incorrect, is—"that it has at last been carried out by a young engineer named Holland, who, it is said, furnished the company with plans of the engines, which plans were submitted by the directors to qualified persons, and having been by them deemed feasible, they were placed in the hands of Mr. England for realization."

During the last Session of Parliament, a bill was applied for for powers to construct a railway nearly parallel with the Festiniog Railway, which was, at that time, and had been for many years, worked by horses; and the principal reason for the new company applying for their bill was, that they intended to introduce the locomotive into that district, their line being intended to be 4 ft. 8½ in. gauge, while the existing Festiniog Railway was only 2 ft. gauge, which, they endeavoured to show, might be well enough for working with horse-power, but was utterly incapable of being worked by locomotive power, quoting the opinion of various engineers to that effect.

I heard Mr. England give evidence before the Committee of the House of Lords on the 6th of May (Lord Stanley in the chair), when he stated he was then constructing locomotive engines for the Festiniog Railway Company, who were then opposing the scheme. Their strong point of opposition was, that they intended to work their line with locomotive power, which, although their line was only 2 ft. gauge, they felt assured would be of sufficient power to supply the requirements of the district; and with a view of satisfying the Committee upon that point, they had called Mr. England to give evidence, who stated that he had been entrusted with the construction of the engines by the company, and assured the Committee that they would not only do their work well, in proportion to their weight, but would be equally safe in going round the sharp curves at the intended speed they were to run, as any locomotive at present in work.

He further stated that the centre of gravity was precisely the same as that of a number of engines he had recently made for the Great Western Railway Company, which were then running daily, at the rate of 50 miles an hour, and that the small engines would be absolutely safer on the narrow guage at the speed they required to run (namely, six miles an hour) in going round the sharp curves, than the larger engines were, at the rate of 50 miles an hour.

In cross-examination, Mr. England was asked by the counsel for the intended line, "having evidently been well crammed with opinions of various engineers, which he no doubt believed," if he really thought they would work? When Mr. England cut the matter short by stating emphatically that he would stake his existence upon it.

They then attempted to show that the engines which were then being constructed by Mr. England, had been designed by an inexperienced engineer, a mere youth, having evidently got some information of the part that Mr. Holland had taken in the matter. Mr. England replied, that the young engineer had nothing whatever to do with the design of the engines, but that he (Mr. England) alone was responsibe to the Company, both for the design and construction of the engines. He had contracted to make the engines for the Company, under a guarantee that they should work trains weighing 25 tons up their line, with gradients of 1 in 70, at a speed of six miles an hour; and he felt quite confident of the result.

Mr. England having satisfied the Committee on these matters, the result was, that the bill for the competing line was thrown out.

I was present and heard the evidence, which may be found in the Minutes of the Committee of the House of Lords.

It is certainly gratifying to find that the assertions of Mr. England have been more than realized, as I learn that the engines are daily working upon the line between Festiniog and Port Madoc, and taking a load of 50 tons up these inclines, at a speed of 12 miles an hour, being just double the weight and double the speed that he had contracted for; and he is at present constructing, at his extensive works, New Cross, two more engines precisely of the same dimensions, and from the same drawings, for the same Company, which I doubt not he will be very glad to show to any one interested in these matters.

I remain, Sir, yours very truly,
John Braithwaite, C.E.

Sir,—Our attention has just been directed to a paragraph in your Magazine for Nov. 27th, giving an account of some small locomotive engines recently set to work on a railway of 2 ft. gauge, extending, from the Festiniog slate quarries, a distance of 13 miles, to Port Madoc, in Carnarvonshire.

After stating that several eminent engineers, including the late Robert Stephenson, had been consulted and pronounced against the practicability of working this line by locomotives, you proceed to say that a "young gentleman," Charles Mendez Holland by name, had successfully carried out what Stephenson had expressed his inability to perform.

On October 28th, 1862, we were invited to tender for these little engines. A tracing and specification were supplied; and we are not the least surprised to find that they were the production of . "young gentleman, 21 years of age."

Now, the construction of *small* locomotives for narrow gauges and special purposes has been our *particular study and occupation* for several years past; and it so happened that, in the ordinary course of business (and not as a great feat), we had previously designed an engine for a gauge of

1 ft. 11 in. (the Festiniog gauge being 1 ft. 11½ in.); a modification of this design and specification, accompanied by a diagram showing that the centre of gravity was more favourably placed than in the Great Northern express passenger engines running at 45 miles per hour; and that, therefore, the little engine would be perfectly safe at 8 miles per hour—we say this design and specification were submitted to Mr. Spooner, the resident manager at PortMadoc, and admitted by him to be far superior to those of the "young gentleman." Indeed, so satisfied was Mr. Spooner, that he proposed to lay the plan before his directors, and on November 20th, in reply to an inquiry, wrote us, "I think, in all probability, the Company will adopt *your* plan of locomotive for the Festiniog Railway; but you will hear from me again on the subject." The next news we have is what we read in your MAGAZINE of November 27.

On the Festiniog line the ruling gradient is 1 in 92, and the steepest 1 in 75. We have engines daily working on inclines of 1 in 30 and 1 in 32; and Mr. Ramsbotham has long had an engine of 18 in. gauge running about the works at Crewe. Now it follows either that the Festiniog Slate Company did not adopt the one which their manager admitted to be the *best* design; or, if they did, then that design is *ours*, and has been handed over to another firm to carry out. Which is the more likely alternative, we leave with the public and yourself to decide. At any rate, one thing is quite clear, that it required no great effort of genius to design a locomotive to work on a 2 ft. gauge upon an incline of 1 in 75, and that Mr. Charles Mendez Holland is not the *only*, not even the *first*, man in Great Britain who has designed such an engine.

We are, your obedient servants.
MANNING, WARDLE, & Co.

Boyne Engine Works, Leeds,
December 8, 1863.

[We beg to remind our correspondents that the notice in question has appeared in other papers as well as the MECHANICS' MAGAZINE; and although we inserted it as an example of one of the narrowest locomotives in the world, we in no way identify ourselves with the sentiments and opinions expressed by the writer.—ED. M. M.]

Miscellanea.

A prospectus has been issued of the General Floating Dock Company, for the construction of floating docks, chiefly in France, but also elsewhere, upon a principle invented by M. Couran. The first operations are to be at the port of Bordeaux.

On the 28th ult., the "Iowa" screw steamship was launched from the building yard of the Neptune Iron Works at Waterford. Her dimensions are—length, 330 ft.; breadth, 35 ft.; depth, 27 ft.; burthen, over 3,500 tons. The "Iowa" is the property of that enterprising firm, Messrs. Malcolmson Bros., Waterford, and the well-known enterprising A. G. Robinson and Co., Mark-lane, London, and intended for the Havre and New York line. She is fitted with all the modern scientific and mechanical appliances—superheaters, waterheaters, condensers, steam winches and cranes, Horn's patent valves and steering apparatus, also Suffield's engine-room telegraphs; and in her construction no expense has been spared to render her complete for her station. This splendid ship was designed by Mr. Horn, the manager of the works, and is the twentieth steamship he has added to their extensive fleet.

Gen. D. C. McCallum, formerly Superintendent of the Erie Railroad, is now the United States Government Engineer of Railways. Lately there was accomplished under his direction, a feat without a parallel in railroad construction. The 30 miles of railroad recently destroyed by Lee's army, was rebuilt; and, in doing so, the ties were prepared, and the main track and switches laid, 600 ft. of bridging (some of which was 60 ft. in height), 20 culverts, and 10 water tanks constructed, all within the space of three weeks!

The Festiniog Railway, in North Wales, a line 14 miles long, with a uniform inclination of 1 in 80, and a gauge of only 2 ft. was opened recently for traffic with locomotive power. The engines, which only weigh 5 tons, are the smallest ever made for railway traffic. They are beautiful, low-built, compact four-wheeled coupled tank engines, with cylinders 8 in. in diameter, and wheels 2 ft. in diameter. At the opening of the Festiniog Railway each engine conveyed a train of about 30 tons weight up the line and round curves of 130 ft. radius at a speed of 13 miles per hour with perfect ease.

A passage is said to have been just discovered near the city of San Fernando peculiarly fitted for a railway, which, by means of the Santiago line, would establish a direct communication between Chili and the Argentine Republic. The Chilian Government have directed a staff of engineers to examine the route.

The public lamp-posts at Paris, which are of cast iron, are being coated with copper, by electro-depositing, so as to have all the effect of bronze. The large fountains in the Place de la Concorde have recently been taken to pieces in order to be thus covered. The work is done by M. Oudry, at Auteuil, who is carrying on electro-depositing on a gigantic scale. He has recently completed a full-sized copy in copper deposit of Trajan's Column at Rome.

It is worthy of remark, in designing screw propellers, that those wheels which have a medium proportionate diameter, a medium pitch and proportionate fraction of the pitch in surface, or in length of the hub, give better results than extreme diameters, very quick pitches, and large working or superficial area on the blades. Experiments, carefully conducted, prove the truth of these statements.

The United States iron-clad steamer "Winnebago" left St. Louis on the 20th October, on a trial trip, under the command of Chief Engineer James W. King, U.S.N., Superintendent of Iron-clads in the West. She was operated on 72 consecutive hours, the engines making 67 revolutions per minute, and the propellers 112 revolutions. With this speed of screw, the vessel sailed 9 miles an hour in smooth water. The "Winnebago" is the first of four sister propellers launched, and considerable anxiety was therfore manifested in the result. It is gratifying to know that everything worked satisfactorily. The vessel is of iron, 220 ft. long, 56 ft. wide, and 7 ft. deep. She has two fore-and-aft bulkheads and six thwart-ship bulkheads, all water-tight. She has two turrets, one Ericsson's and the other Ead's patent. The latter turret differs from Ericsson's, among other things, in having a portion of the shell entered down to, and the whole weight of the turret resting on spheres at the bottom of the vessel. The guns are placed on a huge platform, loaded in the hold, and raised in the turret by steam power. They are also run out by steam; the recoil is received on steam cylinders, and the whole apparatus, guns and all, is operated by one man (an engineer), no other person being needed in the turret. The loading is accomplished by loaders below the turret, in the hold.

Mr. Maclise is making steady progress with his great water-glass picture in the Royal Gallery, Houses of Parliament. An immense quantity and a vast variety of detail occur in the background of such a subject as "The Death of Nelson;" rigging, masts, sails, implements of naval war, and a host of minor figures appear there. Nearly all the still-life accessories, some minor figures, and even two or three large ones, are completed

The name of Azulene has been given by Mr. Septimus Piesse to a new body discovered by him to exist in several essential oils. In a Paper describing Azulene, read before the Chemical Society, the author stated that though this substance was first observed by him as a product derived from the fractional distillation of otto of patchouly, he has since found it to exist generally in essential oils, as an integral part of their proximate constitution, giving the colour by which each oil is distinguished. Pure azulene is of a beautiful blue colour, and the presence of a small quantity of it gives the blue oil of camomile its azure tint; hence the name given to the new body. It is now ascertained that brown-green, yellow-green, and green oils owe their colour to a portion of azulene and a yellow resin, varying in proportions, as optically indicated. We cannot, however, view the general presence of azulene in essential oils merely as a colouring matter, but think it must also have some connection with odorous bodies. Sir D. Brewster is now engaged in examining the optical properties of azulene, which are of a remarkable character. He has already announced that it absorbs entirely several well-known lines in the spectrum.

One of the most frequent causes of the bad burning of mineral oil lamps, says the *Grocer*, arises from the employment of damp wicks. Cotton, like most other vegetable fabrics, readily absorbs from one-sixth to one-fifth of its weight of moisture from the atmosphere; this prevents the free ascent of the oil, and leads to charring of the wick, and the production of an imperfect flame; hence it is exceedingly important that a new wick should be thoroughly dried before it is placed in the lamp. When it has once been saturated with oil, the further absorption of moisture is prevented. If our subscribers would point out this small precaution to their customers, both parties would find it of advantage. The trouble of holding a wick before the fire until it ceases to give out any vapour is so trifling as not to be taken into consideration, and the improvement in the flame and the regularity of burning is considerable.

Special postage stamps, says the *Presse*, are about to be issued in Egypt for franking letters in the interior of the country. They are to be manufactured in England by a company which supplies such articles to many of the States of Europe.

The *Montrose Standard* understands that arrangements are making with the Ordnance authorities for the purpose of testing a projectile of a peculiar construction, which has been invented by Mr. James Cobb, police constable, Lintrathen.

A monument, consisting of a column, about 30 ft. high, with suitable inscription at the base, has been erected in Darfield Churchyard, in memory of the 189 persons who lost their lives in the Lundhill colliery explosion in 1857.

Cotton-growing is occupying attention nearly everywhere on the River Plate, and we are promised great things in the course of a few years. The Cotton Supply Association of Manchester has sent out 20 bags of cotton seed for distribution, and several cotton-growing companies have been established in Corrientes, under the auspices of the governor of that province. The Estancieros in other parts of the Argentine Republic have also sown cotton seed with the most hopeful prospects; and in Paraguay the same spirit is beginning to animate the native population. The *Buenos Ayres Standard*, which may justly claim great credit for the energy with which it has promoted the cultivation of cotton in the River Plate, in its European summary refers to the subject as follows:—"Our foreign readers who take an interest in Argentine prosperity will be pleased to know that over three tons of the very best cotton seed of all descriptions have been distributed, and are already planted in the parts of this nation most adapted to the growth of cotton. Our philantrophic and sterling friends in Manchester will hear with delight that millions and millions of cotton plants are at present overground. We promise the English manufacturers 5,000 bales of cotton from the River Plate this season, and 100,000 the next. In payment for our cotton bales we ask neither gold sovereigns, nor ounces, but railway iron, cotton goods, coal &c. There are some who laugh at our predictions; but we will not 'bate one jot.' In a year or two, if we have peace, the River Plate will be to England what the once prosperous United States of North America were—the supplier of staples, the consumers of manufactures. We are all here as yet in our infancy; our future is great; and England is regarded as the best friend of the Argentine nation."

Mr. Mechi, of Tiptree Hall, writes thus to the *Bedford Times*:—With reference to the filthy and dangerous condition of railway cattle, sheep, and pig trucks, let me suggest an easy and uncostly way of cleansing them. A gutta-percha hose and

jet attached to a 6-in. force pump driven by steam power, would effectually cleanse a truck in two or three minutes. I speak practically in this matter, for my own jet worked by steam is of a thousand scrubbing-brush power. Every crack and cranny is almost instantaneously cleansed. Merely drawing it hastily across a hard gravel walk will cut a furrow in it, and I could, when I fed 350 pigs or beasts, wash them all clean in ten minutes within a range of 40 or 50 ft. One of our steam fire engines gives an exact illustration of the operation I desribe. Railway Companies have generally plenty of water and steam power to propel it. The health of our stock is of vast importance, and it becomes a duty due to the public. In fact, legally, I apprehend that if it could be shown that our animals became diseased by railway neglect, we could not fail to recover damages. The jet would answer equally for steam vessels used in conveying stock.

The French telegraph screw-steamer, "Le Dix Decembre," is now lying in the Thames, opposite the factory of Messrs. Siemens, Halske, and Co., at Charlton, taking in the 130 knots of submarine wire destined to connect the Spanish town, Carthagena, with Oran, on the north-west of Africa. The cable is of an entirely novel construction, being protected on the outside by strips of copper, instead of iron wires, as hitherto. It has been manufactured for the French Government by Messrs. Siemens, Halske, and Co., the celebrated telegraph contractors.

Vegetable ivory, in contact with concentrated sulphuric acid, takes a splendid red colour, almost equal to magenta. At first it is pink, the bright red becoming deeper, and attaining a purple when the acid has been allowed to act for twelve hours. Vegetable ivory dust can in this way be readily distinguished from bone and ivory filings. The change is owing to the action of this acid upon albuminous substances in the presence of sugar, and this reaction has been applied by Raspail in microscopic researches. The white portion of cocoa-nut is similarly affected. The red colours disappear in water like the fine reddish-brown colour produced by mixing essence of turpentine with sulphuric acid.

We learn that a proposal has been set on foot, for a Rifle Conference, to be held in the Hall of King's College, London, on Tuesday, Wednesday, and Thursday, January 12th, 13th, and 14th, 1864. The object of this conference is to enable those who are interested in rifle shooting, to consider the management of rifle matches, prize meetings, and other competitions; to impart information as to the apparatus and weapons employed; the targets, marking, and scoring; and the various adjuncts of rifle shooting; as well as to discuss the arrangements and regulations which have been approved by experience, or are suggested as further improvements.

Some interesting experiments have just been made at the Ministry of the Interior in the telegraph offices. The system of typo-telegraphy, invented by Chevalier Bonelli, was tried on the line between Paris and Boulogne-sur-Mer. The results were very satisfactory. In spite of the bad state of the line and wet weather, the impression of the despatches left nothing to desire, either in regard to the good formation of the letters or the rapidity of transmission. By this new system, three hundred despatches per hour may be printed in duplicate, and at very great distances. There is little doubt that it will be adopted all over the Continent.

Patents for Inventions.

ABRIDGED SPECIFICATIONS OF PATENTS.

The Abridged Specifications of Patents given below are classified, according to the subjects to which the respective inventions refer, in the following Table. By the system of classification adopted, the numerical and chronological order of the specifications is preserved, and combined with all the advantages of a division into classes. It should be understood that these abridgements are prepared exclusively for this Magazine from official copies supplied by the Government, and are therefore the property of the Proprietors of this Magazine. Other Papers are hereby warned not to produce them without an acknowledgement:—

1087. J. Wibberley. *Improvements in machinery or apparatus for winding cotton, silk, wool, or other threads on spools or reels.* Dated April 30, 1863.

In carrying out this invention, the patentee employs the ordinary right and left-handed screws for traversing the thread from end to end of the spool or reel; but instead of changing the traverse by hand, he arranges it by means of self-acting movements. On the ordinary sliding shaft which carries the right and left-handed nuts, he places an arm extending to the top of the machine, and passing through a sliding box working on a plate, which box carries at each side a slide, having connected to it a catch, and the two catches alternately seize and hold the upper part of the arm and maintain the nut upon the screws, the arm being moved alternately from one screw to the other, and also from one catch to the other, by causing it to be acted upon by inclines or cams placed under the plate which carries the sliding box. The two slides on the sliding box are acted upon by a rod connected to the upper part of the guide stock, and the rod which carries the stock works in a bearing fixed to the ordinary sliding shaft, so that a slight revolving motion may be given to the stock alternately in different directions each time the guide comes in contact with the ends of the spool or reel. This revolving motion of the stock places the guide in an angular position adapted to right or left traverse of the thread, and also gives movement to the slides on the sliding box, and relieves the catches alternately from the top of the arm on the sliding shaft, in order to allow one or other of the nuts to be in action. He also employs a lever, put in motion by self-acting means for shifting the driving strap from a fast to a loose pulley on the driving spindle when the desired number of layers have been wound on the spool or reel. The lever is fixed to a stop or setting-on rod carrying a strap fork, and acted upon by a spring, and one end of the lever is held in a detent when the strap is on the fast pulley. On the sliding box there is a ratchet wheel and measuring plate carrying a lifter for raising the lever out of its detent, and allowing the spring to shift the rod and strap fork and stop the machine. *Patent completed.*

1088. A. H. Remond. *An improved process for retaining the aroma of coffee and cocoa.* Dated April 30, 1863.

The nature of this invention consists in giving to the coffee berries and cocoa nibs during the roasting operation a coating of such a material as will fill up the pores of the berry and prevent the escape of any aroma whatever therefrom, but at the same time will impart no disagreeable flavour thereto. The agents preferred are a white sugar, and a thin mucilage of gum or gelatine, either in conjunction or separately. *Patent abandoned.*

1089. W. Clark. *Improvements in the manufacture of hydrocyanide of ammonia and of alkaline and earthy cyanides.* (A communication.) Dated April 30, 1863.

The patentee claims—1, the reaction, at a red heat, of ammoniacal gas on soot or lamp-black, or, preferably, carburetted hydrogens, or other matters producing at a high temperature carbon in a nascent state; 2, the production of hydrocyanide of ammonia and its transformation into cyanide with a base of lime, potash, soda, or of metallic oxide; 3, the simultaneous passage of the ammonia, carburetted hydrogen, or napthaline, over a mixture of charcoal and alkaline carbonate heated to redness, as described; lastly, the method of producing the carbon necessary for the formation of the cyanogen in a nascent state, and in intimate mixture with the ammonia, by the decomposition of a hydrocarburet or other matter capable of producing the carburetted vapours. *Patent completed.*

1090. E. Mitchell. *Improvements in reaping and mowing machines.* Dated April 30, 1863.

This invention consists in the employment of horizontal knives (with three or more blades) or cutters, with or without serrated edges. These knives or cutters are fixed one on each side of the machine, and upon the same level and close to the ground. They are made to travel in opposite directions, motion being given to the said knives or cutters from the driving wheels by means of suitable gearing, such as pulleys and straps or bands, spur or bevel wheels, or frictional gearing. Each knife or cutter has a separate motion with an apparatus to disconnect it from the driving wheel. In advance of the machine, and in front of each knife or cutter, is fixed a wheel, so arranged that it will raise or depress the said knife or cutter, and keep it clear of all obstacles or irregularities of the ground. *Patent abandoned.*

1091. E. G. Brewer. *Improvements in welding and rolling metals and in machinery connected therewith.* (A communication.) Dated April 30, 1863.

This invention consists in welding bars of iron or steel, as hereafter described, so as to form bars of iron or steel of large dimensions perfectly homogeneous. For this purpose the cylinders of the rolling mill are corrugated, or fitted on their external circumference with projections which compress the longitudinal joints of the bars forming the mass, and force them to become welded one with other, when the mass heated to a convenient temperature is passed between the said cylinders. In order to keep the mass laterally at the time the pressure is applied to produce the welding, the rolling mill is provided with rollers set vertically, and on the sides laterally and tangent with the end of the said rolling cylinders. These vertical rollers are intended to keep the metal on the side, and to prevent it from escaping laterally under the effect of the strong pressure it receives while passing between the cylinders; the bars are by this means welded one to the other in every direction, and a homogeneous mass is obtained. *Patent completed.*

1092. C. P. Stewart and J. Kershaw. *Improvements in engines, machinery, and apparatus for containing compressed air, and for applying the power thereof in propelling railway and other carriages.* Dated April 30, 1863.

This invention relates—1, to engines and machinery or apparatus for compressing air, and consists in a combination and arrangement of machinery or apparatus by which air is compressed by the action of water or other liquid having a reciprocating motion imparted to it by a piston or plunger actuated by a piston or pistons worked by steam or other motive power. One feature of the improvements consists in applying the power of the steam or other motive engine so that, when the piston or plunger actuating the water is at one end of its stroke, the piston of the steam or other motive engine will be about mid-stroke. By this means the piston of the steam or other motive engine will be at its greatest speed or power when the piston compressing the air is at its slowest speed, and has the greatest resistance to overcome. Another feature of the invention consists in compressing air at several operations by means of water actuated by steam or other motive engine, that is, in compressing the air in the cylinder, then transferring it to another cylinder of smaller area, where it is further compressed, and so on till it has attained the pressure required. *Patent completed.*

1093. J. Appleby. *Improvements in propelling ships and barges.* Dated April 30, 1863.

This invention relates to a peculiar arrangement of propellers for ships and barges, and consists in the application and use for that purpose of two or more screw propellers or helices, having their respective blades placed at opposite or reversed angles, such propellers being carried on two or more separate shafts, one or more of which are placed at each side of the vessel, and at right angles to the keel; or two or more may be placed on each side of the stern-post or midship. A sufficient space or opening is left between each set of helices or screws to allow the dead water to escape, the propellers acting not as screws but as paddles. By this arrangement the loss of power from back water is obviated, and the speed of the vessel will much depend upon the rapidity with which the screws are worked, thus overcoming a difficulty always met with in the ordinary paddle wheels now in use. *Patent completed.*

1094. J. H. Johnson. *Improvements in rotary engines.* Dated April 30, 1863.

This invention relates to the general arrangement of that class of rotary engines wherein two discs set at an angle opposite to each other are rotated by the direct action of cylinders and pistons upon their inner faces, and consists, according to one arrangement, in connecting the centres of the two inclined discs by a shaft and universal or ball joints, whereby the discs will work in concert without the intervention of toothed gearing upon their peripheries working in corresponding toothed wheels on a second motion shaft, which arrangement may be used if desired; but when employed it is requisite, in order to obtain the best action of the gearing, that the angle of the teeth be not less than 36 deg., nor more than 45 deg. *Patent abandoned.*

1095. J. F. Gray. *Portable apparatus or instruments for rivetting, caulking, chipping, and otherwise operating upon and treating vessels and other substances.* Dated May 1, 1863.

In machines constructed according to this invention, the hammer head or striking part is fitted in the cylinder so as to form a loose end thereof, or an end not rigidly connected therewith, and it is not connected to the piston. The piston is itself an independent bolt or hammer of suitable weight traversing back and forth shuttle-like in the cylinder, and communicating its force to the hammer head by impact within the cylinder. By this arrangement the hammer head is almost stationary, and therefore the length of the machine is much reduced, and the hammer head can be kept in contact with the material to be operated upon, which is an advantage in certain kinds of work. This loose end of the cylinder may be either a hammer head or "tool head" or "tool holder," or a "swage," or other tool, and will be hereinafter referred to under the name of "tool." The invention consists—2, in providing improved modes whereby the slide valves of impact machines when applied to the purpose hereinbefore referred to may be operated self-actingly at each stroke of the piston. These modes consist—1, in an arrangement of inside tappets; 2, in an arrangement whereby the slide valve is moved in one direction by an inside tappet, and in the other direction by the direct action of steam and piston connected with or forming a part of the slide valve; 3, in an arrangement whereby the slide valve is moved in both directions by the direct action of steam upon pistons connected with or forming parts of the slide valves, or communicating motion thereto; also in adapting such impact machines to the operations of rivetting required in the construction of iron ships, bridges, and other uses, by fitting them with suitable contrivances for attaching, disconnecting, and holding up, so as to constitute efficient portable rivetting machines; 4, in adapting such impact machines to the operation of chipping, caulking, planishing copper pipes, thinning the edges of copper plates, and in adapting it to be used as a portable steam hammer; 5, in providing a convenient portable boiler and rivet hearth by combining in one apparatus the boiler, the rivet hearth, a furnace common to both, and a feed injector. *Patent completed.*

1096. E. Jones. *Improvements in drainage and in water-closets, and in the means and apparatus necessary for the same respectively.* Dated May 1, 1863.

We cannot here give space to the details of this invention. *Patent abandoned.*

1097. W. Clissold. *Improved apparatus for fulling woollen cloths and washing and cleansing woven fabrics.* Dated May 1, 1863.

This invention relates to the application to machines employed in fulling cloth and washing and cleansing lengths or bands of woven fabrics of a certain mechanical means for imparting a temporary twist to the fabric under treatment immediately before it enters the fulling or pressing rolls, the object (when fulling cloth) being to prevent the permanent formation of creases during the fulling operation. *Patent completed.*

1098. W. G. CRAIG. *Improvements in feed apparatus for steam boilers.* (A communication.) Dated May 1, 1863.

This invention consists in certain improvements upon the feed apparatus known as Giffard's injector. The invention is not described apart from the drawings. *Patent completed.*

1099. J. BADARD. *Improvements in the preparation of rape seed, cake, linseed cake, poppy-seed cake, niger-seed cake, and ground-nut cake.* Dated May 1, 1863.

In order to avoid liability to damage, the patentee submits these cakes after they come from the press, and when they are in the state in which they are usually sent into the market, to a desiccating or drying process. He places the cakes in frames or racks in a drying chamber at a temperature, by preference, of about 180 deg. Fahr., and he keeps them in this chamber until all or nearly all the moisture which will evaporate from the cakes at this temperature has passed off; about twenty-four hours is a suitable time. The cakes are then taken out of the chamber and packed or stored. This process does not in any way injure the cakes as food for cattle, and will enable them to bear keeping for a considerable time without deterioration. *Patent completed.*

1100. T. L. BISSELL. *An improved apparatus for charging breech-loading cartridges.* Dated May 2, 1863.

This invention relates to an apparatus designed for the purpose of charging and turning over the edge of cartridges or cases such as are used with breech-loading firearms, which apparatus is constructed as follows:—To a frame of suitable form the inventor connects a hollow fixed tube in which the cartridge or case to be charged is placed through an opening formed in the front or side thereof. Inside the upper part of this tube is a second hollow tube capable of sliding vertically therein, to the upper end of which is attached a reservoir which is divided in the centre so as to contain powder in one side and shot in the other. Between the reservoir and the last named tube, and in connection with both, is a chamber (also divided in the centre) having two lever chargers, as used in ordinary shot belts or pouches, to measure the quantity of the charge admitted at a time. To the same frame he also attaches a small vertical spindle capable of being revolved by a winch handle, and carrying a hollow inverted cup for turning over the edge or muzzle of the cartridge case, the case itself being supported at the back by a semi-cylindrical piece fixed to the frame, and resting at the bottom on a moveable socket attached to a lever, by means of which it may be pressed gradually upwards against the revolving cup, by which means the closure of the muzzle of the cartridge case is effected in a much more regular and efficient manner than has heretofore been accomplished. *Patent abandoned.*

1101. W. T. SMITH. *Improvements in washing machines.* Dated May 2, 1863.

This invention consists in the employment in or over a trough, or other vessel, of one or more grooved rollers, to which motion is communicated by a treadle and crank through an endless belt or toothed gear. The person washing works the roller by the foot, while with the hands the clothes or articles to be washed are kept in or pressed in contact with the grooved roller. The projections or parts between the grooves act as beaters, and remove all dirt from the articles, after having been more or less soaped and soaked in water in the usual manner. In some cases the inventor also uses a plain roller, upon which the clothes or other articles rest while being acted upon by the revolving beaters. *Patent abandoned.*

1102. J. W. GIBSON and W. TURNER. *Improvements in springs to be used for railway buffers, draw hooks, and also for carrying springs of railway carriages and other vehicles.* Dated May 2, 1863.

This invention relates to the employment for the above-mentioned purpose of volute springs or bars of steel, or their equivalents, in connection with the certain special arrangements for twisting or winding up such springs or bars of steel, thereby affording the requisite power of resistance. *Patent abandoned.*

1103. G. BURT. *Improvements in machinery for punching, stamping, or forging metals.* Dated May 2, 1863.

This invention consists in the construction of a machine which shall operate as a direct-acting hammer, having the advantages of being able to increase the power of the blow at will, to throw the hammer easily in and out of gear, to raise the hammer when it is either in or out of gear, and to increase or reduce the length of the stroke given by the hammer. *Patent abandoned.*

1104. J. PURDEY. *Improvements in breech-loading fire-arms.* Dated May 2, 1863.

This invention relates to that description of firearms in which the barrel of the gun is made to turn on a horizontal pin, so as to raise and expose the end or breech of the gun, in order that a cartridge may be placed therein. The invention consists of a novel mode of securing or locking the barrel when it is brought down into a horizontal position on the stock ready for being discharged. For this purpose a locking bolt, forming part of a sliding bar working through the body of the action, enters two slots or notches in the steel lump on the under side of the barrels. This locking bolt forms part of a sliding bar which is worked by a lever placed in the middle of the body, and made to fit snugly in or against the trigger guard. A projection on the lever, or the tail or upper end of the lever, works through a slot in the sliding bar, which is kept up to its work by one or more springs acting either at the back of the bolt or against the lever, or both, as may be found most advisable. The bolt that forms part of the sliding bar, and also the end of the steel lump, are both bevelled, so that in the action of closing up the barrels the bolt is first made to move back, and when the barrel is in its place the bolt is by means of the spring made to slide forward and lock the gun securely. *Patent completed.*

1105. S. J. BARTLETT. *Improvements in apparatus for straining and drawing off liquids.* Dated May 2, 1863.

This invention relates to a cheap and simple contrivance to be fitted to tea and coffee urns and other vessels employed in the preparation of infusions and decoctions, also to cisterns, tanks, or vats, whereby the infusion or other liquor to be obtained and drawn off is obtained in a clear state. In applying this invention to an ordinary or other urn intended to be used in the preparation of infusions of tea or coffee, an inverted cup or bell of metal, porcelain, or other suitable material is to be placed near the bottom of the urn with its mouth downwards. To the top of this bell or inverted cup is fitted a syphon pipe curving downwards outside the cup to a little below the mouth thereof, and then entering the ordinary or other draw off tap or cock. A strainer or filter of perforated metal, wire gauze, or other suitable material is placed in the mouth of the cup. In preparing coffee or tea by this improved urn, the coffee or tea is first introduced into the bottom of the urn, and the hot water is then poured in over the bell or cup. The air therein is rarefied and expanded, and escapes in the form of bubbles from under the lower lip, thereby keeping the coffee or tea agitated for a short period, and allowing it to be well saturated by the hot water. So soon as the grounds have settled, the infusion is ready to be drawn off through the tap, the tap pipe and cup or bell forming together a syphon, and the liquid is consequently obliged to rise before it is drawn off, in place of descending, as is the case in most other arrangements where the receptacle is above the vent, and where the heavier particles pass away with the liquid. *Patent completed.*

1106. J. B. DUBREUIL. *Improvements in carts, waggons, and other vehicles.* Dated May 2, 1863.

This invention consists in a method of constructing carts, waggons, and other similar vehicles, whereby they are rendered capable of weighing their contents. *Patent abandoned.*

1107. J. T. and T. OAKLEY. *Improvements in the construction of garden pumps, part of which said improvement is applicable to fire engines and other hydraulic machines.* Dated May 2, 1863.

This invention is carried out as follows:—Within a vessel somewhat similar in form and size to an ordinary pail when inverted, and to the bottom thereof, the patentees adapt a rectangular-shaped wooden box, fitted with a suitable valve or valves, and one or more pump barrels open at top, and fitted with a piston or pistons packed or otherwise, so as to work water-tight inside the barrels. The rods of these pistons are made to work vertically by suitable handles, or they may be connected to a horizontal lever working on a pin or fulcrum in a piece of wood fixed upright in the aforesaid vessel; there is a loose pipe connected to the aforesaid box. The suction is within the aforesaid vessel or attached by a union to the outside of the same. There is also connected to the aforesaid box an air vessel formed of vulcanized india rubber, or other suitable elastic material, which when the pump is in action becomes distended by the compressed air as the water is forced therein, so that in addition to the force of the compressed air in the air vessel the patentees obtain and utilize the elastic force of the distended india-rubber air vessel, which materially increases the power of the pump, secures a velocity of flow, and forces a column of water to a greater height than when the air vessel is made of metal, as heretofore practised in the construction of force pumps. *Patent completed.*

1108. H. MYERS. *A new apparatus for indicating appointments or fixed engagements.* Dated May 2, 1863.

This invention consists in the employment of a circular clock dial, arranged in suitable divisions, and with hands for indicating the appointment or fixed engagement. *Patent abandoned.*

1109. E. R. SOUTHBY. *Improvements in the extraction of scents from plants, flowers, and other odoriferous substances.* Dated May 4, 1863.

In carrying out this invention, the inventor extracts the odoriferous part of plants, flowers, and other scent-yielding substances, by dissolving the same in the light spirit derived from petroleum and other native oils, or from coal shale and other analogous substances by destructive distillation, and commonly known as Ettierine. *Patent abandoned.*

1110. J. FORTUNE. *Improved means of joining or fastening together lace, blond, quilling, or similar materials.* Dated May 4, 1863.

This invention consists in joining or fastening together pieces of lace, blond, &c., by means of gum and a hot iron. *Patent completed.*

1112. B. G. SLOPER. *Improvements in apparatus for separating metals from earthy and other matters mixed with them.* Dated May 4, 1863.

This invention consists in constructing apparatus as hereafter described, wherein the matters acted on are first separated according to their degrees of fineness, and are afterwards subjected to washings, whereby the metals and metallic particles are left in receptacles from which they are afterwards removed. The apparatus consists of a perforated cylinder, the perforations in which are gradually reduced in size from one end of the cylinder to the other. This cylinder is made to revolve over, and partly in, a cistern or vessel containing water, and in which funnels are placed for receiving the matters as they issue through the perforated cylinder. These funnels are fixed into, or form part of, tubes fitted at the bottom with taps which open into syphon pipes of india rubber, or other suitable flexible material. An agitator is placed under the bends of these pipes, and keeps them constantly in motion. *Patent completed.*

1113. G. HASELTINE. *Improvements in springs for railway carriages and other purposes.* (A communication.) Dated May 4, 1863.

This invention relates, chiefly, to the use of longitudinally fluted bars in the construction of spiral or helical springs, to the novel modes of combining india rubber or similar material with metal in the formation of springs for supporting heavy weights or resisting great pressure, to a novel construction of the parts whereby the strength is greatly increased and the weight diminished, and to so arranging the parts as to augment the elasticity of the spring by means of confined air. The required elasticity of the composed spring is obtained by the use of a spiral spring in connection with india rubber or similar material, or by the use of one or more concavo-convex springs and india rubber, or by the employment of india rubber in connection with confined air. *Patent completed.*

1114. F. APPLEGATE. *Improvements in spring balances and pressure gauges.* Dated May 4, 1863.

Instead of using dial and index hands or pointers pointing to the graduations on a disc or other dial plate in these instruments, the inventor makes the dials or indicators of such apparatus of a plain opaque surface covering the graduations of the dial, which are visible through an opening, glazed or otherwise, through which the reading of the gauge is obtained, such opening passing over the graduated dial or surface either of a circular or of a lengthened form, and the indicator (that is, the plate with the opening) either rotating or moving in a direct line as usual. *Patent abandoned.*

1115. J. H. JOHNSON. *Improvements in the manufacture of wrought iron and steel, and in the apparatus to be employed therein.* (A communication.) Dated May 5, 1863.

This invention relates to the manufacture or production in a blast furnace of wrought iron and steel direct from the ore, and consists, essentially, in injecting or blowing into the furnace with the blast finely divided oxide of iron. *Patent completed.*

1116. W. WALSH. *Improvements in obtaining and purifying oxalate of soda, which improvements are also applicable to the manufacture of oxalic acid.* Dated May 5, 1863.

This invention consists in submitting woody fibre or other organic substances to the action of caustic soda alone. The patentees uses caustic soda known as dry or solid caustic soda, containing from 60 to 70 per cent. of caustic alkali, and submits it to a temperature of from 450 deg. to 800 deg. Fahr. in a crucible or cast-iron vessel, so that it can be liquified without admixture of water, and thereby obtain a fluid of the before-mentioned strength. This fluid is removed from the crucible to another vessel, and the woody fibre or other organic substances placed in it, and agitated by hand or machine. On account of the great heat and strength of the caustic soda lixiviation takes place, and forms with the woody fibre a pulp which is a crude oxalate of soda. This pulp is afterwards dried, and contains 20 to 30 per cent, of oxalate, whic his purified and converted into oxalic acid in the ordinary manner. *Patent completed.*

1117. R. G. KENT. *Improvements in the construction and arrangement of shades and reflectors for gas lights.* Dated May 5, 1863.

This invention relates to certain improvements whereby the light obtained from fishtail, batswing, oval, argand, or other gas burners giving a flame of an elongated form, is more perfectly diffused and reflected than by the arrangements hitherto in use. The shades which are constructed in accordance with this invention are of an eliptical form, the material employed being either glass or porcelain, and are used in combination with such burners as before mentioned. The shades are fixed and adjusted by means of suitable fittings. The result of the employment of the shades constructed and employed as before mentioned, is that the rays of light diverging from every portion of the elongated flame are duly transmitted and reflected, and the whole of the illuminating power of the flame is thus made available. The reflectors are also constructed of an elliptical form, and are formed of glass or metal, or combinations of glass and metal, or of any substance or substances possessing the requisite powers of reflection, and the surfaces thereof may be either smooth, cut, or corrugated, so as to reflect the rays of light in any desired direction. The reflectors are placed in any desired position with reference to the flame, and may be used with or without the shade as may be desired. *Patent completed.*

1118. E. CHESSHIRE. *Improvements in apparatus for intercepting the solid portions of the soil of water-closets.* Dated May 5, 1863.

This invention consists in the use of an apparatus consisting of a vessel or reservoir placed or constructed in the course of the soil pipe or drain, passing from the water-closet to the drain or main sewer, the said vessel or reservoir being divided by a perforated pipe, plate, or grating into two compartments, the soil pipe or pipes from the water closet or closets opening into one of the said compartments, and the drain or sewer pipe opening into the other of the said compartments, the said perforated pipe, plate, or grating intercepting the solid portions of the soil, and retaining them in the vessel or reservoir, and permitting the liquid portions to pass through to the drain or sewer pipe. *Patent completed.*

1119. W. BOOTHROYD. *Improvements in stationary engines or apparatus for obtaining motive power.* Dated May 5, 1863.

In carrying out this invention, the inventor employs a cast-iron or other suitable framework, the top of which is provided with four pulleys or wheels for carrying a horizontal or main shaft. On this horizontal or main shaft are fixed two bosses, each boss having four arms, the arms being connected together by four plates or cross bars extending from arm to arm on each boss. On the said horizontal or main shaft he also employs a spur wheel geared into another spur or pinion wheel fixed on a cross or counter shaft. The said cross or counter shaft is provided with a toothed wheel, geared into another toothed wheel for the purpose of giving motion to an eccentric tappet or lever attached to a carriage for pulling and pushing two or more weights on and off the before-named plates or cross bars.

He also employs another shaft with suitable gearing, one end of which receives motion from the toothed wheels on the cross or counter shaft, and the other end by means of another pair of toothed wheels gives motion to two rollers. These rollers are provided with chains or ropes for lifting the weights when pulled off the plates or cross bars into their proper position. These rollers turn in opposite directions by means of three bevel wheels, two of the bevel wheels being loose, so that either one or the other may be put into gear as required. Above the framework he fixes a carriage and tramway with a sheave pulley attached for the purpose of the chains or ropes to work over, the said carriage being moved to and fro by the eccentric tappet or lever. He also employs a break wheel for regulating the speed as may be required. *Patent abandoned.*

1120. R. A. BROOMAN. *A new fabric suitable for trimmings.* (A communication.) Dated May 5, 1863.

This invention consists in manufacturing in pieces or in strips a new fabric, by sewing, stitching, or otherwise applying birds, feathers on a ground of linen, cotton, or other like suitable foundation. The feathers may be of one colour or variegated, and may be made to resemble flowers or other figures, and may be worked into various patterns. *Patent completed.*

1121. F. APPLEGATE. *Improvements in stopping and starting railway trains.* Dated May 5, 1863.

This invention consists in the application of a spring or springs, to be thrown into gear to take up the vis viva of a railway train, which the inventor applies in connection with the wheels of the tender while in motion; at the same time applying a breaking action thereto whereby to stop the train. The spring or springs are by this means wound up in great tension, and are capable of being held in such state of tension and afterwards utilized in overcoming the vis inertiæ of the train in starting. *Patent abandoned.*

1122. P. BRADSHAW. *Improvements in mounting or hanging millstones for grinding grain and other substances.* Dated May 5, 1863.

According to this invention, the patentee makes the centre bar of the runner to carry the pivot, and he causes it to bear on a flat surface on the upper end of the driving spindle; thus it will be seen that the pivot is not confined, as formerly, but can adjust itself accurately to the driving instruments, so that these may be sure to bear equally on each side of the pivot. The pivot might be mounted at the top of the spindle, and the plain surface might be on the centre bar, but this would produce some difficulty in balancing the stone. He prefers to employ, in place of the driving forks before mentioned, lugs or projections on the boss at the top of the driving spindle, and these lugs or projections enter loosely into corresponding recesses in the centre bar. The sides of the lugs or projections he does not make vertical, but to project forward on a level with the plain surface on which the pivot rests, so that the contact for driving the stone, or the bite, as it is termed, may take place only on a level with the pivot, whereby the motion is rendered steadier than it would be if the bite were either above or below the centre. *Patent completed.*

1123. J. H. KNOTT. *Improvements in pumps.* Dated May 5, 1863.

This invention relates to that description of pumps known as rotary pumps. The improved rotary pump consists of a cylinder in which works a piston resembling in form the eccentric gear of a steam engine. The eccentric is mounted on a central spindle, and works in a strap which envelops it. This strap is provided with a tail, which works in a spindle or socket at one end of the cylinder, and thereby forms a stop which divides the cylinder into two compartments, one of which is in communication with the suction pipe, and the other with the exit pipe. It will, of course, be understood that the piston and strap with its tail or stop are made accurately to fit the cylinder, so that when the cylinder head or end plate is secured in its place, the ends of the piston may be water-tight; and, therefore, in communicating rotary motion to the piston shaft, the piston will move in the cylinder and will draw in the water by one pipe and force it out by the other. The spindle through which the tail of the stop passes is fitted water-tight in its socket or bearing, in which it is free to vibrate so as to accommodate itself to the movements of the tail piece. It will be understood that, by this arrangement of parts, all moveable valves may be dispensed with, and that a continuous or nearly continuous suction takes place, and that the pump will act as a force pump as well as a suction pump. *Patent completed.*

1124. W. GLOFER. *Improvements in means or apparatus to facilitate the steering of ships and other vessels.* Dated May 5, 1863.

Upon the axis of the steering wheel the patentee applies another wheel, toothed or otherwise formed to hold the parts of a chain or rope, which is thence guided by suitable pulleys, and has its opposite ends made fast to the circumference of a wheel applied to the rudder head, or to the axis of motion of the rudder. Thus, by acting on the steering wheel, motion is, through the single rope or chain, communicated direct to the rudder. By this means a slack chain is avoided, and the power exerted is more immediately effective. *Patent completed.*

1125. W. C. WILKINS. *Improvements in lamps.* Dated May 5, 1863.

This invention is carried out as follows:—To a lamp constructed with a reservoir in its stem or base to contain the matter to be burned, and means for forcing up such matter for consumption, the patentee applies between such reservoir and the burner a separate small vessel as an intermediate reservoir or receiver for the supply to the wick, and he applies leather or other suitable non-conducting matter between the upper parts of this intermediate reservoir or receiver and the burner tubes. This intermediate reservoir or receiver has an overflow for surplus fluid to flow back into the reservoir below. In some cases he applies several of such tubes concentrically supplied by intermediate reservoirs or receivers, and in order to prevent the conducting of heat to the fluid to be consumed, the wick tubes may be each separated, the upper from the lower parts thereof, except by slight connections, or by the application of non-conducting material between the parts. He also applies an internal hollow cone, and an external tubular deflector, the upper or deflecting edge thereof being turned inwards, and at or near the level of the wick tubes. This external deflector he prefers to be of glass, so as to intercept the rays of light as little as possible; over these he applies an external chimney. He also applies within the main reservoir for the fluid to be burned a pump or working diaphragm, with the crank shaft and wheel-work or other mechanism for forcing up such fluid to the intermediate reservoir and wick or wicks, by which the use of packing is avoided, and simplicity of working is obtained. *Patent completed.*

1126. R. B. COCHRAN. *Improvements in sewing machines, and in apparatus connected therewith.* Dated May 5, 1863.

The patentee claims—1, the general arrangement and combination of mechanism for saving or uniting fabrics, as described; 2, the application and use of a reciprocating shuttle or thread case, driven or actuated in the manner described; 3, the combination with the shuttle and shuttle-actuating mechanism above referred to of a rotating hook and cylinder formed on the end of the driving shaft, as described; 4, the application and use to and in sewing machines of all kinds of two or more tension apparatus, which are permanently adjusted to take certain specified sizes or numbers of thread; 5, the combination with the stitch-regulating mechanism of an indicator and graduated scale for the purpose described; 6, the attaching of the presser foot of a sewing machine to the presser bar by the aid of a slot made either in the bar or in the foot, in combination with a jam nut, whereby it can readily be removed, and another substituted, substantially as described; 7, the peculiar arrangement of apparatus for driving sewing machines, as described and illustrated in the drawings; 8, the peculiar construction of hinges for sewing-machine covers, as described; 9, the constructing of binders for sewing machines in such a manner that they are self-adjusting to any thickness of material, as well as being capable of adjustment to suit different widths of binding, substantially as described. *Patent completed.*

1127. T. SAGAR and J. WILKINSON. *Certain improvements in power looms for weaving.* Dated May 5, 1863.

This invention consists in an improved method of applying the "weft fork" to power looms, whereby the liability of breaking or damaging the prongs of the weft fork is lessened. The slot cut across the lay through which the weft fork traverses does not require to be so large as usual, thereby increasing the strength of the lay at that point, and allowing of wider cloth being woven in the same width of loom. *Patent completed.*

1128. J. T. WARD. *Improvements in carriages.* Dated May 6, 1863.

In carrying out this invention, the inventor makes the body of the carriage of the form of the carriage ordinarily called a "waggonette," the said body of the carriage being provided with moveable raised backs to the seats. He provides a cover for the carriage, which cover being placed upon the body and fixed temporarily thereon, converts it from an open to a close carriage. The said cover has a seat in front, which will accommodate four persons, and is railed round at top so as to fit it to carry luggage. The said cover is provided with windows. As the moveable high backs to the seats are not required when the cover is used with the carriage, the said backs are removed before the cover is put on. The invention consists, secondly, in the addition of a folding or collapsible luggage basket. He names this carriage the "Cawdor." *Patent abandoned.*

1129. W. E. GEDGE. *An improved toy.* (A communication.) Dated May 6, 1863.

This improved toy is composed of a pistol which discharges or launches a top, and of the top itself. There is a small toothed wheel supported on an axle passing in the end of the pistol barrel; a string is rolled round the axle and is attached by the other end to a spring inside the pistol and a small rod (answering to the ramrod of a pistol), one end of which takes into the teeth of the small wheel, the other being attached to the trigger of the pistol. The top itself has a special arrangement; its stem carries a pin which fits into the axle of the small toothed wheel of the pistol, the said axle being hollow, and terminating in a spiral form. *Patent abandoned.*

1130. S. HIBBERT and J. KAY. *Certain improvements in apparatus for cleansing potatoes and in decorticating the same and other esculent roots.* Dated May 6, 1863.

This invention consists in the employment and use of a double arrangement of rotating brushes—one portion thereof being placed upon a central shaft, and rotating in one direction; the other brushes being secured in a perforated cylinder encircling the central shaft, the bristles projecting towards each other, and the cylinder being driven in an opposite direction to the shaft by means of bevel gearing or any other suitable mechanism. The brushes are made to taper towards each other at the lower extremity, so that all sizes of roots will be acted upon, and the potatoes or other roots are placed in the space between the brushes, the action of which cleanses and removes the skin or exterior coating therefrom, the whole being enclosed in a vessel containing water. *Patent completed.*

1131. S. D. MACKELLEN. *Certain improvements in watches and other timekeepers.* Dated May 6, 1863.

This invention relates to that part of watches and timekeepers known as the escapement, and is designed to dispense with the "escapement wheel" as employed in the ordinary "duplex escapements." The invention consists in the use of a horizontal plate or fly, furnished with one, two, or more pointed arms or long teeth, such fly being mounted upon a central vertical shaft carrying a pinion which gears with a toothed wheel, and is driven by the ordinary train of wheels in connection with the finger. These pointed arms or teeth as they revolve take successively into the slot in the balance wheel shaft (which is used in the duplex escapement), and passing out of the slot form the escapement. Upon the fly are secured two or more vertical ruby pins, termed "impulse pins," so arranged that as the escapement takes place they strike a projecting finger on the balance wheel shaft, and give motion and impetus to the balance wheel, and thus a simple description of escapement is constituted. By this means the complicated duplex escape wheel is altogether dispensed with, and the usual ruby roller is rendered unnecessary, as by using the toothed fly the force is diminished so much that the friction on the shaft is very slight. This also permits a wider notch to be cut in the shaft. *Patent completed.*

1132. J. M. SINGER. *Improvements in sewing machines.* Dated May 6, 1863.

This invention is not described apart from the drawings. *Patent completed.*

1133. G. DAVIES. *Improvements in machinery or apparatus for forging and dressing horse-shoe and other nails.* (A communication.) Dated May 6, 1863.

The characteristic feature upon which the present invention is based consists in the operation of four tools placed at right angles, which open and close two at a time, striking in such a manner as to obtain a forging effect analogous to that produced by hand. The tools in working allow of an escape at the side, and it is only necessary to have a special feeding apparatus to the machine so arranged as to supply the necessary amount of iron or material to the tools in order to make the required length. The dressing machine is intended to finish the rods or shanks of the nails, and, at the same time to efface the marks of the tools or hammers, which although they are very slight, are nevertheless perceptible. *Patent completed.*

1134. T. BEESLEY. *Improvements in the construction of boxes or cases for carrying and packing bottles.* Dated May 6, 1863.

According to one arrangement for performing this invention, the inventor takes a case, and near the bottom thereof he fits a frame with as many apertures in it as the case is required bottles to contain. Into these apertures the bottles are placed, their lower ends resting on the bottom of the case, while the frame through which they pass steadies them and prevents their coming in contact with one another. A second frame, containing apertures equal in number, but smaller than those in the lower part of the case, is made to fit the case accurately, and in such manner that the apertures shall pass over the necks of the bottles. The second frame is held in position by thumb screws, or by a handle fitted to its top side, which, when the cover is secured, presses against and so steadies it, while at the same time it acts as a means for readily removing the frame from the case. *Patent abandoned.*

1135. A. STURROCK. *Improvements in locomotive engines and tenders.* Dated May 6, 1863.

This invention consists in fitting auxiliary cylinders and engines on or to the tender, in connecting them through ordinary connecting-rods in the usual manner to the wheels of the tender, in coupling all or some of the wheels of the tender, and in taking steam for the tender cylinders from the ordinary boiler which supplies the engine proper. The invention also consists in forming the water tank in the tender with a false bottom, and in leading the exhaust steam from the tender cylinders into the chamber between the two bottoms. Sometimes, instead of forming the tender with a false bottom, the patentee causes the waste steam to circulate through a coil or series of pipes carried through the water in the tender; this steam heats the water in the tank, and the steam which is condensed in the chamber or pipes returns into the tender and is forced by the pumps into the boiler. *Patent completed.*

1136. C. W. ATKINSON. *An improved steam or other motive power engine.* Dated May 6, 1863.

This invention consists in a certain arrangement whereby the to-and-fro motion of the piston of a steam or other motive power engine is converted into a rotary motion, without the intervention of a crank or other apparatus as ordinarily employed. The arrangement for this purpose consists in bringing pressure to bear alternately on either side of an enlarged head, or on either of two surfaces carried by the piston rod. The rotating shaft which is to receive the converted to-and-fro motion is between such surfaces, and has on either side thereof the apparatus to receive the to-and-fro motion. *Patent abandoned.*

1137. A. V. NEWTON. *Improvements in sewing machines.* (A communication.) Dated May 6, 1863.

This invention is not described apart from the drawings. *Patent completed.*

1138. J. PARK. *Improvements in communicating motion to machinery for manufacturing paper pulp.* Dated May 7, 1863.

This invention is not described apart from the drawings. *Patent completed.*

1139. J. SNIDER. *Improvements in breech-loading fire-arms.* Dated May 7, 1863.

This invention primarily refers to the arrangements for locking and securing the moveable breech piece or charge chamber. The first part of the invention consists in holding and securing the breech piece in place by a self-acting latch bolt centred in such manner that the bolt takes into an aperature provided for its reception so soon as the breech piece is pressed down by the hand. On the discharge of the cam the hammer in falling and striking the nipple comes so near to one end of the lever to which the latch bolt is attached as to prevent the bolt leaving the aperture into which it entered when the breech was closed. The breech is unlocked by pressing a button on the lever in the contrary direction to that in which it was struck by the hammer, and the breech is raised by the hand. The second part of the invention consists in making the fire communication central to the charge chamber. The third part of the invention consists in forming the hinge and breech in one piece, and in making the hole for the hinge pin oval. The fourth part of the invention consists in forming an aperture on the under surface of the breech closed by a screw for the introduction of lubricating material into the valve chamber. *Patent abandoned.*

1140. P. Bourne. *Improvements in miners' lamps.* Dated May 7, 1863.

This invention relates to the lamp known as the "Davy safety lamp," and consists in means for extinguishing the light of the lamp in the act of opening the lamp, and before the wire gauze covering can be removed from the lamp. For this purpose the inventor attaches to the lamp near the wick-holder an apparatus consisting of one or more levers mounted on a suitable fulcrum, bearing or bearings, and which apparatus is capable of being depressed on the wick by the act of removing the wire gauze covering. This apparatus is, by the action of a suitable spring or springs, or by the weight of the short end of the lever or levers aforesaid, or by both of such means, kept out of the way of the ignited wick so long as the gauze covering remains on the lamp, or when the gauze covering is being placed on the lamp; but as soon as any attempt is made to remove the gauze covering, one or more small projecting piece or pieces attached to the mounting of the gauze covering is forced under the short arm of the lever (or of each of the levers if more than one), which short arm is thereby, and by the unscrewing of the gauze covering, elevated, and thus the other end of such lever (or levers) is depressed on the wick, and so the wick is pressed down and the light becomes extinguished. *Patent abandoned.*

1141. J. Walker. *Improvements in the construction of mechanism applicable to looms and carding engines and other machinery.* Dated May 7, 1863.

This invention relates, firstly, to the construction of eccentrics or cranks, their connecting links or rods, and their combination with the driving pulley disc or other mechanism, such mechanism being applicable to looms, and to the doffing motions of carding engines, and to other machinery where eccentric or crank motions are required. The improvements consist in making the connecting links or rods with a slit in them lengthwise from the hole in which the eccentric or crank works, and in placing a screw through the link or rod so as to be able to close or open the slit, and thus tighten or slacken the grasp of the link or rod upon the eccentric or crank. The second part of the invention relates to the taking-up rollers of wrought sheet iron, or in covering them with wrought sheet iron on the surface when rolled cold or hot by being passed through rollers which have roughened surfaces. *Patent abandoned.*

1142. A. Stanley. *Certain improvements in the mode of finishing clasps and other such like metallic connectors, and which said mode of finish is also applicable to other purposes.* Dated May 7, 1863.

This invention consist in finishing metallic clasps and such like connectors by covering them with leather, either on one or both sides, the said leather being moulded, pressed, or embossed to the shape or sectional design of the metal shell or part desired to be covered, and which leather is intended to be united around the edges to the metal portion or part or back covering by stitching or sewing, which may be effected by hand, or with the aid of the sewing machine, or otherwise secured; and in some instances the inventor purposes adding on the outer surface of the leather central or other ornaments, which may be secured by wire shanks soldered or otherwise united to the ornament, and passed through the leather covering metal shell or other material and back covering, when back coverings are used, to be spread over or rivetted or secured in any other convenient way. *Patent abandoned.*

1143. G. Bower and A. Dick. *Improvements in the purification of gas ordinarily used in illuminating, and in the reduction of ores and smelting of metals by means of such gas so purified.* Dated May 7, 1863.

This invention consists in the employment of heated iron sponge for the purpose of decomposing and removing sulphurous compounds which may be contained in coal gas. The commonly purified coal gas retains small quantities of sulphurous compounds, particularly of sulphuret of carbon, which render it unfit to be employed for metallurgical purposes. By this invention, all sulphur compounds and impurities are decomposed and removed by the action of heated metallic iron in a porous state. *Patent completed.*

1144. T. Small. *Improvements in motive power machinery.* Dated May 7, 1863.

The object of this invention is to gain power by combining together and with certain other mechanism a system of levers. The following is an example of the said combination:—In a suitable framing the inventor adjusts by pivot or fulcrum a lever of the first order; the longer arm of this lever is fitted into an eye or socket formed in a double toothed rack, which has vertical reciprocating motion imparted thereto by two sector wheels having teeth thereon which take or gear respectively into the teeth of the aforesaid double rack; the said sector wheels are mounted on an axis or shaft, and one of said sectors is fast on the shaft, the other sector being loose thereon. These sectors have rotary motion imparted thereto in opposite directions by a bevelled pinion taking into the teeth of bevelled wheels fixed to or formed upon the aforesaid sector wheels, or otherwise connected therewith. The aforesaid sector wheels are so placed with respect to each other, that, when one sector is in action, the other is out of action; the rotation of one sector raises the double rack before mentioned, and actuates the lever connected thereto, and the other sector depresses the rack, and moves the lever in an opposite direction, thus imparting continuous vibrating motion to such lever. The short arm of the lever is connected by a rod to a crank fixed on a shaft, on which is arranged another set of wheels and sectors, similar in all respects to those above described, and gearing into another double rack similar to that above mentioned, and in this manner any number of levers may be connected together. Motion is imparted to the above mechanism by a handle or pulley fixed on the axle of the first set of wheels, and worked either by hand or by a steam engine. The inventor also proposes to adapt a fly-wheel to each of the separate sets of wheels aforesaid to carry the cranks past their null points. *Patent abandoned.*

1145. J. Bettridge. *Improvements in the ornamentation of papier mache and other japanned wares, wood, ivory, and other similar materials.* Dated May 7, 1863.

This invention consists in inlaying articles of papier maché, or other japanned wares, wood, ivory, or other similar materials, with aluminium or its alloys, by which the patentee obtains ornaments in imitation of the more precious metals, such as gold or silver, without their liability to tarnish, with less weight, and at much lower cost. *Patent completed.*

1146. C. A. Day, A. Lamb, and T. Summers. *Improvements in marine engines.* Dated May 7, 1863.

This invention consists in the employment of the ordinary suction air-pumps of steam engines, either for screw or paddle steam vessels, for the purposes of surface condensation, in manner hereafter stated. The patentees apply the two ordinary suction air-pumps of steam engines to surface condensers in such manner that one pump draws from them the condensed or fresh water for the supply of the boilers, and that the other pump draws from them the sea water or condensing water, which it discharges overboard. *Patent completed.*

1147. J. B. P. A. Thierry. *Improvements in the arrangement or construction of furnaces to render the combustion of the fuel more complete, and to prevent the emission of smoke therefrom.* Dated May 7, 1863.

The object of this invention is to procure a more complete combustion of the fuel in the furnaces, and to prevent thereby the emission of smoke. This the patentee effects by blowing in against the bridge of the furnace, by preference, from the front of the fireplace, through one or several jets, superheated dried steam, which, being by intense heat freed from its water, offers to the fire a gaseous combination of carbonic acid gas, oxygen, and azote, and so intensifies the combustion as to prevent the emission of smoke. The steam so used should be at a temperature of about 300 to 600 degrees Fahrenheit. *Patent completed.*

1148. T. Holliday. *An improved blue colouring matter.* Dated May 7, 1863.

This invention consists in obtaining a blue colouring matter by the combination of rosaniline with the benzoate of aniline, or combination of benzoic acid with aniline or its homologues, or mixtures of them. *Patent abandoned.*

1149. P. J. Livsey. *Improvements in compound steam engines.* (A communication.) Dated May 8, 1863.

This invention consists in connecting the piston of the high-pressure cylinder with the beam, so that it will have a larger stroke than the piston of the low-pressure cylinder. Or the invention consists in combining the high and low pressure cylinders with the beam of the engine, so that the low-pressure cylinder will be at one end, and the high-pressure cylinder at the other end of the beam, the connecting rod for the crank pin being placed between the high-pressure cylinder and the fulcrum of the beam. *Patent completed.*

1150. A. Skwarcow. *Improvements in the construction of turn-tables.* (A communication.) Dated May 7, 1863.

This invention consists—1, in bolting or rivetting lengths of railway bars on the under side of the H-iron beaters at the point where the short pieces of the bearers butt against, or are connected to, the long pieces, by which means the strength of the cross bearers is carried through from one side to the other, and the bearers made continuous. 2, In forming the centre spindle on which the table revolves of wrought iron, and of such a form as to allow the horizontal plane of the table to be out of the square with the vertical axis of the spindle without bringing any bending strain on the spindle. 3, In forming the oil cup or box in the same piece of metal as the spindle, and in fixing in the centre of the oil cup a steel stud, upon which rests another steel stud which is fixed to the wrought-iron cap of the table. By this arrangement the surfaces of contact of these two steel studs are always working in oil. And, lastly, in connecting the circular rail with the casting of the central spindle by means of round wrought-iron rods. *Patent abandoned.*

1151. H. Schooling. *Moulding or shaping lozenge paste or other plastic materials.* Dated May 8, 1863.

This invention consists in the adaptation of various well-known machines, now in use for other purposes, to cut, mould, or shape various pastes or plastic materials, but more particularly the article known to confectioners as lozenge paste, into a variety of new forms, notably the adaptation of pill-making machines for making lozenge pills, rolls, oblongs, sticks, pipes, and other shapes, and the adaptation of machines for drawing lead and metal tubes to the drawing of lozenge tubes or hollow pipes. *Patent completed.*

1152. J. S. Grimshaw. *Improvements in looms for weaving.* Dated May 7, 1863.

This invention consists in measuring or registering the measurement of cloth as it is woven in the loom. This the inventor accomplishes by fixing on the emery beam a wheel or wheels with a marker or indicator, so that as the said wheel turns with the emery beam a certain number of revolutions, the marker or indicator will mark the cloth every yard or other length required as it is woven. Or it may be measured by a marker or indicator on the temple, or various other parts of the loom, but it is preferred to measure by the emery beam. *Patent abandoned.*

1153. C. L. Braithwaite and J. Hirst. *Improvements in machinery for feeding slivers of wool and other material to carding engines.* Dated May 8, 1863.

This invention consists in the employment of a V-shaped frame in the feeding apparatus used in carding engines for feeding the slivers to the machine, and in driving the shuttle by toothed gearing and chain bands, all as described. *Patent completed.*

1154. J. H. Bailey. *An improved mechanical movement for producing an impelled current of air for lamps, and which may be used for other purposes.* (A communication.) Dated May 8, 1863.

This invention is not described apart from the drawings. *Patent completed.*

1155. J. C. Droop. *An instrument or holder for holding nails, screws, and other fastenings.* Dated May 8, 1863.

This invention consists in magnetizing or applying magnetism in connection with a tool called a "tack or nail holder," by which means tacks, nails, or other similar fastenings may be picked up and held by magnetic attraction in the right position for driving with a common hammer or screw driver. The picking-up part of this "tack or nail holder" the inventor prefers to construct with a claw, and having a collar of india rubber, gutta percha, or other suitable non-conducting material, to prevent the tacks, nails, screws, or other fastenings adhering thereto, otherwise than to the exposed magnetized part of the "nail holder" which is presented to the tack, nail, or screw to be picked up. *Patent abandoned.*

PROVISIONAL PROTECTIONS.

Dated September 17, 1863.

2288. C. H. Chadburn, 71, Lord-street, and W. J. Tristram, 34, Adlington-street, Liverpool. Improvements in the construction of ships and other vessels, and in the machinery for propelling them.

Dated September 28, 1863.

2383. J. Bailey, turret clock manufacturer, Salford, G. W. Blake, agent, Manchester, and W. H. Bailey, turret clock manufacturer, Salford. Improvements in barometers, gas regulators, and other apparatus for regulating and indicating the flow and pressure of liquids and fluids.

Dated October 13, 1863.

2514. A. Crellin, Dorset-place, Dorset-square. Improvements in apparatus applicable to omnibuses in order to indicate the number of persons entering such vehicles, and the distances travelled by the passengers.

Dated October 19, 1863.

2557. L. Eynard, 48, Langham-street, Portland-place West. Improvements in brakes for railway trains and other purposes.

Dated October 23, 1863.

2617. J. Ronald, Liverpool, merchant. Improvements applicable to the machinery used for spinning hemp, flax, manilla, wool, and other like long fibrous material from the hand, or when previously formed into a "sliver."

Dated October 24, 1863.

2632. A. and W. P. Potter, Longfleet, Dorsetshire. Improvements in railway waggons for the transfer of minerals and general merchandize.

Dated November 2, 1863.

2709. T. Adams and J. Scott, 14, Little Tower-street, stationers. An improved kind of envelope for the transmission of patterns or samples of merchandize by post.

Dated November 3, 1863.

2716. J. Mackintosh, North Bank, Regent's-park. Improvements in taps or cocks for liquids or gases.

Dated November 6, 1863.

2756. R. Saunders, Croydon, gentleman. Improvements in fastening together the parts of ships and vessels, and in respect to the more efficient caulking of the seams thereof.

Dated November 12, 1863.

2810. B. A. Murray, Manchester, machinist. Improvements in machinery for doubling, twisting, and winding silk and other fibrous substances.

2812. A. Craig, Rock Ferry, Birkenhead, engineer. Improvements in distilling hydro-carbons from coal, shale, and other bituminous substances, and in apparatus employed for that purpose.

2816. H. Holden, Preston. Improvements in shuttles for weaving.

2819. W. E. Gedge, 11, Wellington-street, Strand. An improved process and apparatus for amalgamating the precious metals. (A communication.)

2822. L. E. C. Martin, 32, Albion-street, Hyde-park. Improvements in apparatus for generating steam.

Dated November 13, 1863.

2826. C. W. Siemens, Great George-street, Westminster. Improvements in apparatus for submerging submarine telegraph cables. (Partly a communication.)

2828. W. Robertson, Manchester, engineer. Certain improvements in machinery for spinning and doubling.

2830. G. Remington, Haverstock-hill, member of the Institution of Civil Engineers. Improvements in atmospheric or pneumatic railways, and locomotive engines to be used in connection therewith.

2832. W. F. Dearlove, 263, Goswell-road. Improvements in means or apparatus for effecting the chopping or separation of animal and vegetable substances.

2834. J. W. Drummond, New York, United States. Improvements in looms for weaving.

2835. G. K. Geyelin, civil engineer, 17, King-street, Cheapside. Improvements in the construction of water-closets.

2836. G. T. Bousfield, Loughborough-park, Brixton. Improvements in apparatus used when rolling blinds, maps, and other articles on rollers. (A communication.)

Dated November 14, 1863.

2838. M. A. Muir and J. McIlwham, Glasgow, machinists. Improvements in looms for weaving.

2839. J. Medway and S. Joyce, 15, Owen's-row, manufacturing chemists. Improvements in the manufacture of starches by the introduction of colouring matters.

2842. J. P. Binns, Guildford-place, Farringdon-road. Improvements in sewing machines.

2844. J. C. Wilson, 14A, Cannon-street, civil and mechanical engineer. Improvements in cotton gins on the roller principle.

2848. T. S. Prideaux, 209, Piccadilly. Improvements in the construction of armour for ships of war and land batteries.

2850. W. A. Lyttle, 5, Priam-place, Albion-road, Hammersmith, gentleman. Improved covers for umbrellas, parasols, or sunshades.

2852. W. E. Newton, 66, Chancery-lane, civil engineer. Improvements in the treatment or manufacture of wrought and cast iron and steel. (A communication.)

2854. J. Lewis, Elizabeth, United States. Improvements in rudders.

2856. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in presses for lithographic and other printing. (A communication.)

2858. R. A. Brooman, 163, Fleet-street, patent agent. Improvements in engines and boilers specially applicable for agricultural purposes. (A communication.)

2860. T. Williams, 232, Bolling-street, Bowling, York, and I. Naylor, 13, St. James's-square, Horton, Bradford, worsted spinners. Improvements in paper spools or tubes used in spinning and doubling machines.

Dated November 16, 1863.

2864. C. Pengelly, Bodmin, mining engineer. Improvements in mechanism or apparatus for reducing or pulverizing ores and other substances required to be reduced or pulverized.

2866. G. Thonger, Birmingham, chemist. Improved modes of preventing accidents arising from the sale or use of poisons.

2868. R. Griffiths, Mornington-road, Regent's-park, engineer. Improvements in propelling ships or other vessels.

2869. A. Pollock, H. and R. T. Power, Liverpool, merchants. An improved method or apparatus for affixing labels on bottles, canisters, and other like articles.

2870. G. T. Bousfield, Loughborough-park, Brixton, Surrey. Improvements in the manufacture of cartridges. (A communication.)

2872. J. J. Maurer, Paris, France, gentleman. Improvements in towing boats and other vessels.

2874. C. W. Harrison, Battersea, civil engineer. Improvements in filters.

Dated November 17, 1863.

2876. P. M. Parsons, Blackheath, civil engineer. Improvements in the construction and manufacture of ordnance, parts of which are applicable to small arms.

2878. W. Cowan, Edinburgh, Mid Lothian, gas meter manufacturer. Improvements in gas meters.

2880. J. Betteley, Liverpool, iron merchant. Improvements in sheathing ships and other vessels.

Dated November 18, 1863.

2883. R. Mayer, Birkby, near Huddersfield, gentleman. Improvements in breech-loading firearms, and in bayonets and cartridges connected with the same.

2886. W. M. Williams, Oak Alyn, near Wrexham, manufacturer. Improvements in apparatus for the distillation of coal and peat, and such other substances as are or may be used for the manufacture of solid and liquid volatile hydro-carbons, or for the manufacture of the said hydro-carbons and coke.

2888. W. Wigfall, Sheffield, brush manufacturer, and G. Jolly, brush maker. An improved explosive compound to be used in the manufacture of cartridges, and an improved mode of manufacturing cartridges therewith.

2890. J. Stewart, Leigh, boiler maker. Certain improvements in steam boilers or generators.

2894. H. Hirzel, doctor of philosophy, Terminus Hotel, London-bridge. Improvements in the manufacture of colouring matters suitable for dyeing and printing.

PATENT APPLIED FOR WITH COMPLETE SPECIFICATION.

Dated November 30, 1863.

2998. M. R. Pilon, United States. Improvements in firearms.

NOTICES OF INTENTION TO PROCEED WITH PATENTS.

From the *London Gazette*, December 8, 1863.

1861. J. W. Welch. Sizing and finishing fabrics.
1874. J. Jewell. Setting boilers.
1857. P. H. Girardin. Lamps.
1882. E. Sturge. Coating metallic surfaces.
1883. G. Inskeep. Mill for grinding bones.
1887. J. B. Howell. Ordnance firearms and projectiles.
1889. G. Smith. Buffing and traction apparatus of railway carriages.
1891. T. Apps. Four-wheeled vehicles.
1893. G. Sigl. Force pumps.
1902. R. A. Brooman. Dyeing mixed animal and vegetable fibres. (A communication.)
1904. G. Taylor. Shaping boiler and other plates.
1909. E. Sutton. Fastenings for cigar cases, &c.
1913. J. W. P. Field. Sheaths or cases for staves.
1919. J. Abrahams. Brakes.
1921. G. Stevens. Apparatus for effecting a regular supply of air.
1125. W. E. Newton. Moulding and casting hollow projectiles. (A communication.)
1953. J. H. Johnson. Preventing sea sickness. (A communication.)
1958. E. Morewood. Coating metal.
1984. W. Gray. Certain parts of reaping machines.
1996. W. Clark. Lamp for burning coal oil. (A communication.)
2006. H. Brown. Burners for lamps.
2023. E. Scott. Regulating the speed of engines. (A communication.)
2026. E. Lord. Preparing, spinning, and doubling cotton.
2036. J. Smith. Finishing woven fabrics.
2091. H. Batt. Roughing horseshoes.
2151. A. V. Newton. Sewing by machinery. (A communication.)
2300. H. C. Huskinson. Buttons.
2561. W. Ingham and I. Wood. Copper rollers.
2676. O. C. Evans. Digging machinery.
2731. J. A. Barral and L. A. Coohery. Manure.
2752. R. Sellar. Harrows.
2784. N. Thompson. Stopping bottles.
2809. G. Haseltine. Endless chain horse-powers. (A communication.)
2834. J. W. Drummond. Looms.
2836. G. T. Bousfield. Apparatus used when rolling blinds, maps, &c. (A communication.)
2837. T. Harrison. Machinery for cutting and excavating coal.
2838. M. A. Muir and J. McIlwham. Booms.
2839. G. T. Bousfield. Cartridges.
[illegible] W. Wigfall and G. Jolly. Cartridges.

The full titles of the patents in the above lists can be ascertained by referring back to their numbers in the list of provisional protections previously published.

Opposition can be entered to the granting of a patent to any of the parties in the above list who have given notice of their intention to proceed, within twenty-one days from the date of the *Gazette* in which the notice appears, by leaving at the Commissioners' office particulars in writing of the objection to the application.

LIST OF SEALED PATENTS.

Sealed December 4, 1863.

1407. W. A. Brown.
1410. C. E. Newcomen.
1412. N. Walton.
1415. W. Clark.
1419. W. E. Gedge.
1423. H. Reynell.
1426. J. Petrie.
1442. W. Roberts.
1450. T. M. Harrison.
1451. M. Henry.
1455. C. L. V. Tenac.
1465. F. A. and F. Calvert.
1466. G. Davies.
1477. J. Jones.
1479. T. Wrigley.
1489. S. S. Robson.
1492. J. Forrester.
1530. R. Jobson.
1531. E. Gossiaux.
1551. J. L. Clarke.
1555. W. L. and T. Winans
1556. W. L. and T. Winans
1557. W. L. and T. Winans
1558. W. L. and T. Winans
1565. W. Snell.
1573. W. E. Newton.
1773. M. Henry.
1776. D. C. G. Clemm.
2041. R. Baillie.
2129. C. Harratt.
2228. E. Oliver and G. Myers.

Sealed December 8, 1863.

1443. T. Adams.
1446. T. Evans and E. Hughes.
1470. G. Bedson.
1471. T. C. March.
1473. R. Hughes.
1480. J. Hopkinson.
1483. T. A. Elliott.
1486. M. B. Westhead.
1488. H. G. W. Wagstaff.
1490. J. Shand.
1501. J. J. Shedlock.
1502. F. S. Williams.
1509. A. J. Fraser.
1570. W. L. and T. Winans
1571. W. L. and T. Winans
1572. W. L. and T. Winans
1589. S. Knowles and R. Hayward.
1593. S. Smith.
1651. J. King.
1666. H. A. Bonneville.
2245. M. Gerstenhöfer.
2546. J. H. Johnson.

PATENTS ON WHICH THE STAMP DUTY OF £50 HAS BEEN PAID.

143. J. Jobson.
2947. A. Jackson.
2959. W. Pilkington.
2960. W. and J. Galloway
2963. E. T. Hughes.
2980. C. S. Duncan.
2982. C. W. Siemens.
2985. E. Morewood.
3009. J. Robson.
3010. R. Mushet.
3017. D. Annan.
3030. R. Mushet.
3045. R. Mushet.
3070. R. Mushet.
3138. J. Chatterton and W. Smith.

PATENTS ON WHICH THE STAMP DUTY OF £100 HAS BEEN PAID.

2861. F. Siemens.
2867. A. and W. Bullough.
2874. J. Apperly and W. Clissold.
2884. D. Crawford.
2894. W. H. Bowers.
2915. T. Vicars, sen., T. Vicars, jun., T. Ashmore and J. Smith.
2916. T. Peake.
2935. T. and W. Wheatley

MECHANICS' MAGAZINE.

LONDON, FRIDAY, DECEMBER 18, 1863.

THE PRIZE SYSTEM.

Certain institutions may be found in every nation, which, having outlived the necessities which called them into existence, have ceased to retain their original value, and remain in being only by the prescriptive right of antiquity and the prejudices or likings of a class. The system of giving prizes to men, or things produced and invented by men, on particular occasions, is one among many such institutions. It takes its rise far back in the mists of the past—so far back that the history of its origin is lost in doubt—the wreath of laurel given to the victor in the Olympic games, presenting us with one of the first instances of its periodical application to the attainment of a particular end. From the ancient to the modern world is but a step after all; and we find the customs of the past, existing with us in the present, under a modified form, suited to our tastes and our wishes.

The main lever employed by the Royal Agricultural Society to move the engineering world has been the prize system—medals and money for the "most excellent," and money without the medals for the next in rank, and so on down the scale to the zero of "honourable mention." Nor has the lever been wanting in power. There is little room for a doubt that the system has been effective in improving implements, engines, and agricultural mechanism generally, up to a certain point. But there is room for grave doubt as to whether it will continue to be effective, while the laws governing the administration of the Society's justice remain in their present form. Fifty years ago the operations of the farmer derived, literally speaking, no assistance from the labours of the engineer. The ploughwright enjoyed his local reputation for the excellence of particular instruments, and the carpenter and his mates, turned out waggons and carts which answered the purpose for which they were intended passably well. There was no opening for the engineer. Thrashing or ploughing machinery was useless in the absence of the motive power which could alone enable it to fulfil its mission. There was, therefore, no possible motive for designing or constructing it. We doubt, too, if high rents and keen competition held out a stimulus sufficient to make the farmer regard innovation with favour. Times change, however, and just when our Continental neighbours began to find it worth while to supply Manchester and Leeds with breadstuffs, the advent of the portable steam engine brought new men on the scene, and the mechanician taught the agriculturist, how to win more bread and more gold from his land than he had dreamt of; and since then the engineer has been the British farmer's best friend.

But the British farmer does not always know what is good for him; and if this is, and has been, true as regards those questions of social ethics with which he should be best acquainted, how much more likely was it that he should form an incorrect estimate of the powers and qualifications of a class of implements and machines in which he was devoid of experience? An engine or a thrashing machine, a corn drill or a chaff cutter, might do its work well, and yet not so well as the implement of a rival maker. But the farmer, who seldom wanders far from home, was not very likely, if left to his own unassisted judgment, to form a substantially-correct opinion on such matters. And here, wisely and thoughtfully, the Agricultural Society determined at once to provide for the consequences of this ignorance or inexperience, and stimulate the engineer to the production of implements and machinery best adapted to the wants of the agriculturist by the donation of prizes, which were tantamount to a diploma of merit to the receiver. The benefit once experienced, the example was quickly followed, and the spread of Agricultural Societies all over the country has been something very remarkable. It is questionable, however, whether their labours in the implement department, have been productive of anything like as much good of late years as they were previously, and the total abandonment of the prize system has been subject for deep consideration with many, during the last year or two.

Mr. Chalmers Morton has recently given his opinion on this subject to the world, in a Paper read before the Society of Arts; and, if long experience and careful thinking can impart value to sentiments, those expressed by Mr. Morton are well worthy of attention. In the course of his Paper he places the evils attending the prize system as conducted by the English Agricultural Society, prominently before his readers. On the one hand, he shows that the decision of the judges is but too often pronounced after a trial under conditions which preclude the possibility of forming a correct estimate of the powers of the machine under probation, and that on the other, the work performed by various implements—ploughs especially—is often so nearly identical, both in quality and quantity, that a decision in favour of any one is unjust to the remainder. As a natural result, medals and money prizes have lost much of their value as exponents of merit, and the public attach little importance to their possession by individual firms to the exclusion of others. This does not prove that the system is wrong in the abstract; it is only wrong in its mode of application. In the infancy of agricultural engineering, very simple and crude tests were quite sufficient to determine the qualities, good or bad, of the implements exhibited. This state of things did not last very long however. The standard of excellence was rapidly arrived at by one great firm after another, until the difficulty became, not to decide which was most meritorious, but if a really appreciable difference had any existence at all. The tests which were employed ten or a dozen years ago, are useless now; and as a result, either the entire arrangements for the giving of prizes must be altered and extended, or the practice done away with altogether, unless, indeed, the Society prefer to present a portion of their funds yearly to the engineers who graciously send implements to their shows. In such a case, perhaps, the names of the recipients might as well be decided by lot as in any other way. The fact is, that the time for agricultural prizes has passed away. The English farmer can now bring past experience of his own and his fellows to bear; and we question if the decision of judges or committees influence his purchases to any considerable extent.

The bearing of the system on the proceedings of the engineer, seldom comes before the public; yet the question assumes a very peculiar aspect when considered in this light. Morally it has done harm. Had such a thing as a portable engine no existence, this might not have been the case, at least to the same extent; for most other machines must be really good in themselves in order that they may do good work, and little or nothing would be gained by bad workmanship or materials. But, unfortunately, it is not so with the steam engine, on which the vitality of the homestead, to a great extent, depends. The portable, which best performs its work during the few short hours of trial to which it is exposed in the show-yard, may be, of all others, the worst suited to meet the requirements of the farmer over a series of years. The world at large knows little or nothing of the anatomical peculiarities of many an engine which has borne away the prize from a host of competitors. The careful dissection of a "racer," would reveal many a little circumstance, sufficiently startling; while the investigation of its history for the few months before the season of its display would reveal the expenditure of an amount of ingenuity highly creditable to all concerned. The young hands usually have a fair chance at this kind of work. We know of instances where a prize is given in the drawing office, now and then, for the best design for a "racer." and happy is the individual whose engine takes a medal. The practice is not universal, neither is that of building this class of engine; and we are thankful that such is the case, as the custom can hardly be considered conducive to the honesty of the rising generation of agricultural engineers. In addition to this, the expense of attending shows regularly is something enormous. Mr. Morton states that the expenditure of one firm in the this way has amounted to £30,000, and that of another to £20,000; while the spoiling of the best men, and the disorganization of the work, are past estimate. We know who pays such bills as these—not the firms, but their customers.

Shows would not be deserted, even in the absence of prizes. In the first place, it is well worth the maker's while to bring his wares before the public. Some firms have a character to make; others that already made, to maintain against all comers; and good names and high reputations may be won and lost at a show, without the interference of an authorized judge, or the giving or withholding of a gold medal. Novelties are of little value unless they are brought before the public, who can now pretty well discriminate for themselves. The Smithfield Club Show, held last week, affords an example. The display of implements and machinery was one of the best we ever witnessed; yet the inducement held out by the prospect of taking a prize, had nothing to say to the presence there of engine or thrashing machine, cultivator or plough, nor is it necessary that it should. It requires no committee to point out the merit of such an invention as that involved in Barnard and Bishop's lawn-mower, wherein a single ring, covered with vulcanized rubber, performs the work of a train of complicated gearing; the good qualities of Burgess and Key's McCormick's sheaf-reaper, or the "Jack-in-the-box" driving gear of Clayton and Shuttleworth's colossal traction engine. Such things must, after all, stand or fall by the decision of the great mass of purchasers, and not by that of a limited number of judges, however able, talented, or industrious they may be. The working of any machine under show-yard conditions is a very different affair from working it on an extended scale in the open country; and if prizes are really to retain their value as guides to the intending purchaser, it can only be by extending the system of examination by committee, to the homestead and the cornfield, to the rick side and the fallow—a system far too costly, we fear, to pay, although the results obtained would be all but invaluable to the agricultural world.

ROLLING STOCK, AND ITS MAINTENANCE.

MEN seldom spend money in vast sums with a strict regard to principles of economy. This is true, even when the spender enjoys the rights of proprietorship in the fullest sense. It is yet more true of public bodies who have the disposal of funds really belonging to others; and the larger the sums, the greater the disregard for economy. The fact is, that the mind is prone to forget small things in the presence of those which are great; and the interests involved in the expenditure of a million may be so vast, that the waste of a few hundreds is easily passed over almost without comment. Yet a million is but an aggregate of units, and the absolute waste of a single sovereign is as much to be deprecated as though it formed an important instead of a very trifling part of the sum. It is an infringment of those laws which give vitality to mercantile transactions, and though not traceable to fraud, it is direct evidence of negligence, ignorance, or prejudice. No limited number of men not forming a Government, ever represented such a vast capital as the gentlemen who make up our Railway Boards; and it is, therefore, natural to expect that all their procedings should afford evidence of a certain absence of strict prudence in the management of monetary concerns. But it is to be recollected that Railway Boards and Railway Management are not things of yesterday; that all the aids of science may be invoked at the nod of a director who wishes to improve on existing arrangements; and that the experience had already in railway matters is of the amplest—therefore, it is not unreasonable to expect, that waste may be reduced in every department to the lowest point, to the great benefit of expectant shareholders, and to the great glorification of those who hold the reins of government, in the eyes of the whole world. But it is not so. The rolling stock of the United Kingdom consists of 219,500 vehicles, or thereabouts; and it is not too much to say that these afford just so many examples of uneconomical expenditure—uneconomical in that they are not thoroughly well adapted to the end in view, that they do not answer their purpose as well as other vehicles of a different construction might be made to answer it; and that they cost really more money than they ought, for maintainance, repair, and working. This is a direct defect. An indirect, but not less serious one, is to be found in injury done to that which should be, but is not, permanent way. The system which permits the employment of the heavy carriages, trucks, waggons, and engines now in general use, is merely another instance of that want of economy which, we have said, usually attends on the disbursement of large sums of money; and the amelioration of its defects cannot be hoped for from the aid of science alone, unless some science exists which will uproot prejudice and banish the red tapeism of those who have the power, if they had but the will, to amend matters, reduce wear and tear to a minimum, and thereby ultimately increase dividends by a handsome amount.

The cost of repairing and renewing the rolling stock of our railways amounts to £1,242,714 per annum, or about 8¾ per cent. on the total expenditure of the companies. This is a very considerable sum; but it by no means represents the whole loss incurred. It is probable that all our trucks and carriages are one-fourth heavier at least than they need to be. As a consequence, an equal excess of weight is to be found in our locomotives; and the amount of injury to rails, sleepers, and road, which results from this fact alone, is something which has never yet been estimated. Most of this weight is, of course, the effect of the heavy scantling of every portion of the trucks or waggons, rendered necessary far more by the fearful knocking about to which they are exposed in the process of shunting and making up trains, than to anything else. High speeds, over bad roads, have of course something to say to it; but, after all, not so much as might be thought probable at first sight. Of all the unscientific and irrational ideas which have ever taken possession of the mind of man, that of resisting the mechanical forces called into play by a railway train travelling at speed, by brute force alone, is the most absurd. Imperfections in the road should be humoured by elastic springs, not contended with by heavier wheels and axles, and more massive truck and carriage frames. Wise men in the Potteries will not send their goods by rail, because, although not over fragile, and carefully packed, they get broken by the semi-collisions which go on from one end of a string of unbuffered waggons to the other, every time the train starts or stops. Dead weight, and want of elasticity (or perhaps suppleness is a better word), in carriages, engines, and road, is the curse of our railway system; and until the former is reduced, and the latter provided, transit by steam power will never be all that it should be.

In the absence of anything like direct experiment, it is impossible to say what is the minimum proportion which the weight of a vehicle should bear to the load which it supports. But it is certain that it is not nearly approached on our railways. Perhaps we may except first-class carriages, which can scarcely be made much lighter, and yet retain all the peculiar arrangements in which the modern traveller luxuriates. Those who use first-class carriages are able to pay for the accommodation, and they have a right to enjoy it. Second and third-class carriages could be lightened with advantage. It really is not in the superstructure which contains the paying load that the excess of weight is to be found; but in the under framing, which is thus heavy because the road is bad; and the road is bad because the engines are too heavy for its powers of endurance. Thus each effect becomes, in turn, a cause tending to waste money. The loss on passenger stock is, however, as nothing when compared with that on goods stock. Over 180,000 mineral and cattle trucks may be found on our railways, and scarcely 20,000 passenger carriages and brake vans. These trucks are never fitted up as they should be, were proper regard had to the well-being of the track on which they run. The wheels do not receive sufficient attention, seldom paying a visit to the lathe until the last moment. The springs are flexible, it is true—that is to say, they will bend if loaded sufficiently; but the benefits which they confer have far more existence in the ideal, than in the actual. We should be afraid to say how many are without buffers, and are thereby exposed to shocks continually, which literally pound them to pieces day by day; and as to that care which provides for small defects before they have time to grow into larger ones, goods stock meets with nothing of the kind.

In the complete remodelling of their present goods stock, railway companies would assuredly open up a source of economy not thought much of at present. Trucks are made heavier year by year; and that which once represented 30 cwts., or 2 tons of unpaying load, has now swelled to three times as much. Their numbers increase daily; yet there is no improvement in their construction, or in the mode of working them. As a consequence, they destroy the permanent way; they knock each other to pieces; and are so heavy and unwieldy, that their shunting has become a serious evil at most goods stations. It is difficult to say how many a catastrophe has taken its rise from the utter inability of the officials to get some ponderous vehicle out of the way of a coming train in time. That they have not been few, we feel certain. By the employment of easy springs, good buffers, and tight couplings, the road, as well as the engine, would be spared, and the durability of waggons and trucks materially promoted.

THE ORDNANCE REPORT, 1863, CONDENSED; AND CONCLUSIONS FROM IT.

No. VI.

THE ARMSTRONG SYSTEM.

OUR last number concluded with an exposition, from his own lips, of Sir William Armstrong's arduous labours, as he regards them, in overcoming the difficulty of making hoops of coiled iron. He no doubt was solaced by the reflection that the cost came, not out of his, but out of the public purse. According to competent witnesses, including Mr. Whitworth, Mr. Hulse, Captain Blakely, and the Manager of the Butterley Company, there not only was no difficulty in the processes of manufacturing coils of iron, but they were well known and practised before Sir William Armstrong turned his attention to the subject. The only thing wanted was a plant, on a sufficiently large scale, to manufacture coils for heavy guns. "At Woolwich" (says Mr. Hulse, and he might have added at Elswick), "they had a furnace 90 ft. long; they had coiling apparatus and steam hammers purposely adapted to the work." By these appliances, and not by the inventive genius of Sir William Armstrong, the difficulty he referred to was overcome. At Woolwich and at Elswick, there was no limit to the outlay of capital requisite to enable Sir William Armstrong to carry out his projects, however crude or ill-considered they might be. If he failed in one plan he tried another, till he succeeded; but not at his own expense. He was in the happy position of an inventor supported by a capitalist, who supplies him with any amount of money without grumbling. It is difficult to understand how Sir William Armstrong can conceive himself entitled to any credit for results due entirely to the favour shown to him by the public authorities. It is, on the contrary, a grave reproach to him and to them, that whilst the resources of the State were placed at his disposal without limit, other projectors met with no encouragement, and were even refused a trial of their systems at their own expense.

Sir William Armstrong concludes his own eulogy of his own ideas, and his own merit and success, in producing tubes of coiled iron, with the following peroration:—"This principle of constructing the gun of coiled-iron tubes is that on which I started, and to which I have always adhered. I began with 3-pounders of 5 cwt., and I have ascended step by step to 600-pounders of 22 tons. Now, whatever question there may be with respect to the originality of the idea, I think it must be conceded that the country has, at all events, obtained, through the expenditure that has been made, the development of that principle of construction, which is not only very valuable and important, but which has been carried to a much greater extent than there was any reason originally to anticipate. That this system remains the best that is available, is

recognized by the fact that every inventor in rifling, who wishes to get a gun capable of resisting the highest possible charge, avails himself of it. The safety of the principle, I consider, has been established by the fact that, out of nearly 3,000 guns made on this principle, no one gun has burst explosively; and, in fact, no one gun has failed under the most trying tests, excepting by a gradual process, which has given timely notice of the approaching destruction of the gun, and has prevented any possibility of a dangerous accident."

In this statement there is a series of *non sequiturs*. Firstly, it does not follow, because the War-office, led or misled by Sir W. Armstrong's one idea, would listen to no other, that other ordnance constructors, if that Department had allowed them to compete on equal terms, would not, in nine years (from 1854 to 1863) have introduced a better and more economical plan of making coils of iron, or a better plan of strengthening guns, into the service. Secondly, if the coil system should not prove to be the best—a point on which great doubt exists—"the development of that principle of construction" might have been accomplished simultaneously with the development of other systems with an expenditure infinitely less than three millions, which literally is the price of a *single* experiment. Thirdly, if a better system than the "Armstrong" be introduced, and the mode of construction which "came to be viewed" as the Armstrong is abandoned, which seems to be possible, the development of the principle will be neither "valuable or important," but a positive loss to the country, and highly detrimental to the land and sea service.

In Sir William Armstrong's elaborate defence before the Committee, there is not a word in answer to the serious charge against him and the War Department, that he has received the support of the Government to develope his ideas to the exclusion of all competitors.

Plausible as his statements to the Committee are, they afford abundant proof that, from 1854 to 1863, Sir William Armstrong has had no fixed ideas. During that long period, he has been experimenting with the public money, making frequent changes in his principles and modes of construction. He began with a wrought-iron tube, made from a solid forging, for the inner barrel, which he covered with hoops of coiled wrought iron. This experiment was a failure. He tried steel inner tubes without success; other manufacturers have used them successfully. Finally, he committed himself to the coil system for the *inner*, as well as the outer tubes. "This principle of constructing the gun," he says, "is that on which I started, and to which I have always adhered." And yet he is constrained to admit "that the only alternative lies between steel and coiled barrels of wrought iron." Does not this avowal betray Sir William Armstrong's misgivings lest steel should supersede coiled iron and entirely displace it? Such, in fact, is the opinion of eminent and experienced manufacturers of ordnance. Krupp, of Berlin, makes heavy guns entirely of steel. Whitworth makes the inner barrels of his guns of solid bars; he "would not think of making them of welded iron." Blakely uses steel barrels. The Mersey Steel and Iron Company are unshaken in their confidence in solid blocks of their metal.

If these opinions should prove to be correct, the coil system will be condemned, and all the money spent upon it will be lost to the country. Sir William Armstrong admits that "the only question is whether we can obtain the proper metal for a steel barrel with uniformity of quality." In the mean time, he has committed himself and the country to the coil system. But this question was raised by his competitors eight or nine years ago; and the Government, deluded by Sir William Armstrong's determined advocacy of the coil principle, turned a deaf ear to their proposals.

Here is the point which casts deserved blame on the War Department officials. They would listen to nobody but their one favoured projector, who, having secured the patronage of Sir Benjamin Hawes, the Under-Secretary of War, and allied himself with Mr. Rendel, a family connection of Sir Benjamin Hawes, and Captain Noble, the Secretary of two Special Ordnance Committees which recommended the Armstrong system for adoption, obtained so commanding and influential a position at the War-office, that he was enabled to thwart the endeavours of every other artillerist who made proposals to Government to construct guns, either of coiled iron or on other plans, at the public expense. The consequences of this combination, which conferred a virtual monopoly on the Armstrong party, has been most disastrous to the country. It has left all other plans but the Armstrong coil system untried. The manufacturers of solid masses of metal, whether homogeneous iron or mild steel, have received no encouragement from the Government. If to that important object a tithe of the money lavished on the Elswick Works had been devoted, there can be no doubt that before this time, our manufacturers would have produced homogeneous metal of uniform quality, which is stated to be the great desideratum for the construction of ordnance.

We have already shown from the evidence that the Mersey Steel and Iron Company were, in 1860, on the point of obtaining the required degree of perfection in their solid forgings The Ordnance Select Committee reported that the guns made of blocks of metal manufactured by that firm, after undergoing the usual tests, had "shown an endurance ample for the requirements of the service," and that the guns cost 15 to 25 per cent. less than the Armstrong coil guns. The Committee recommended that six blocks of the Mersey steel should be ordered for further trials; but such was the Armstrong influence at the War-office, that no attention was paid by the Secretary of State to that recommendation; and this proposition, which, if acted upon successfully, would have been fatal to the Elswick monopoly, to use an expressive term which the case deserves, was "burked."

We have entered very fully into the coil principle of construction, because Sir William Armstrong relies chiefly on that part of his system, as entitling him to the gratitude of the country, and as justifying the enormous expenditure incurred in carrying out his plans. We have shown how unfounded is the merit he assumes to himself on that ground:—1st. Because he is not the inventor of the coil system. 2nd. Because many others, if the opportunity had been afforded to them (which was not done), would have produced the same, and, probably, better results than he obtained. 3rd. Because it is by no means certain that the coil plan is the best method of strengthening guns.

We might leave the case of the Armstrong system there, and fairly conclude that it is condemned by the evidence bearing upon the feature which its author chiefly claims credit for. But we should fail in doing justice to the Ordnance Report, and we should leave the *exposé* of the real character of the Armstrong gun incomplete, if we did not refer to the evidence on the methods of breech-loading and rifling, which form essential parts of the combination that "came to be viewed as the Armstrong system." Pursuing the same course as before, we will quote evidence from the Report.

Certainly no witness can be more trustworthy than Colonel William Bethel Gardner, R.A. He is "the Chief Instructor in Gunnery at Shoburyness, has held his present position since May, 1859, and during that period has seen very many experiments tried with Armstrong guns of every calibre." The following is an epitome of the evidence of that valuable officer:—"With *considerable care*, the Armstrong breech-loader would be a useful gun; but I have considerable doubts whether it is so formed as to stand the rough usage of service. The weak points of the gun are the vent-piece and the breech screw—the vent-piece is defective in strength, and the breech screw is liable to injury. At the ordinary practice last week two vent-pieces broke very quickly. Since I have been acquainted with the experiments at Shoeburyness, 60 or 70 vent-pieces have been broken." He explains that to ensure accuracy in fitting the moveable parts of the breech, "the allowance between the nose of the vent-piece and powder chamber should be exactly 2-1000ths of an inch, or 4-1000ths difference in diameter,"—"nobody, or at least, not one man in a hundred, when at all excited, would look, or, in fact, have the means of ascertaining, that those dimensions are exactly true; then, if burr occurs, or if these fittings, when you came to thousandth parts of an inch, are not observed, you will probably have the result which we had the week before last." "On service it would not be very easy to remedy those defects, unless the men are very different from what they are now"—"the recoil is very severe and heavy." "I object to the whole system." "Is your opinion of the weakness of the Armstrong guns solely confined to the vent-piece and the breech screw?—No, I think not; taking the gun as it stands in its best form, supposing the breech screw is strong and the vent-piece strong also, I think that a handful of dust thrown over the breech screw, at any time, would clog it so much as to render it very uncertain in screwing up." "My own impression is that the gun ought to be solid as far as possible." "I very much doubt whether the guns at present constructed could stand blows at the muzzle." Colonel Gardner says that in a trial of smooth-bore against Armstrong field guns at 800 yards, "the practice of the former was as good as the Armstrong—in fact, if I remember rightly, rather better." The sights, he thinks, "are very good; but in action they would not be attended to." "The Armstrong 110-pounder gun has twelve parts; I object to all the parts which require lubrication." "We have, in the last fortnight, destroyed the vent-pieces of five 110-pounders in the ordinary practice, and those vent-pieces had the improvement on the back." "Am I right in understanding that your chief and essential objection to the class of guns of which we have been speaking is to the principle of breech-loading?—Yes." "And that that objection, as you have stated it, may be said to be twofold, arising from the injury to the vents in breech-loading and from dirt?—Yes." "An officer in the China campaign reported:—'*On the morning of August 22, on returning to Shinho, after having bivouacked at Tangku in the rain, the breech screws were nearly completely jammed with rust; and if we had had to renew hostilities at daylight that morning, the gunners, who were already over-fatigued, would have been severely taxed in getting the guns in working order.*' When I read that, I felt confident, in my own mind, that we had got the wrong gun, because this Colonel Barry is a

very good officer, and I am perfectly sure that all proper means were taken by him to have his battery in good order; and, therefore, I think that if he made such a report as that with regard, to what occurred on the morning of August 22, the system must have been a very defective one indeed."

We might cite the evidence of many other witnesses to the same effect; but to do so would be to fatigue our readers with repetitions. No special pleading on the part of Sir William Armstrong, or his advocate in the *Times*, can rebut or alter the force of the foregoing evidence. It disposes of the Armstrong plan of breech-loading in the most conclusive way; we will add the testimony of Mr. Westley Richards, who, at No. 3,991, says, "I think any one having experience in guns would not have breeched a gun in the manner Sir W. Armstrong has done."

With reference to the Armstrong system of rifling, we allude to the breech-loaders, not to the shunt, of which we will, in our next number make special mention—it is needless to use any arguments to prove it is not his invention. The lead-coating compression system he borrowed from Wahrendorff; and the Ordnance Committee, in their Report, designate the rifling of the Armstrong guns as the "old polygroove plan."

Such is the Armstrong system, of which there is nothing original but the moveable vent-piece. All the other parts of the gun are borrowed from the ideas of different inventors; and for the most part have been used before Sir William Armstrong became an amateur artillerist. The wrought-iron coil system has been habitually in use for small arms the last forty or fifty years, and was applied to strengthen great guns before he made his first experiments. The built-up system was practised centuries ago, and renewed from time to time to the present day. The compression system of rifling by combining soft metal-coated projectiles with breech-loading, through the breech screw, is an application of other men's ideas. As to the Armstrong vent-piece, in the opinion of experienced gunmakers and practical artillerists, it is the weakest, the clumsiest, the most dangerous, and the most inefficient of all the plans of a breech-loading gun.

In reading Sir William Armstrong's prolix evidence, which takes the form of an essay on his system of artillery, in all its details, of the construction of guns and projectiles, one cannot avoid being struck by the egotistical assumptions which pervade his statements. To meet the wishes of the Government, to supply the requirements of the country, he only, in his opinion, was the person to be consulted; he only was to plan and produce the guns and projectiles of every class and denomination, which, at a time when war was imminent, might be called for. In a tone and style of language, which looks like mockery at the discomfiture of the manufacturers who were excluded from any chance of competition with Elswick, Sir William Armstrong urges as a conclusive argument that, "The Report, as you are aware, was completely in favour of the Armstrong gun and ammunition; and I really must be allowed to observe that I do not see how it possibly could be otherwise. The fact was, that no rival system of construction was brought before that Committee, therefore, on neither of those subjects could the Committee exercise any choice whatever. It may be said, that the Committee might have taken more time; and I would observe, that it would have been infinitely more satisfactory to me if more time could have been allowed to enable me to perfect all the details of the system which I had proposed. But the urgency of the case was such, that this was impossible. There was, therefore, no alternative but to decide and proceed at once."

There never was a more complete case of a man taking advantage of the wrong he has done to justify the ruinous consequences resulting from that wrong. The country was placed in jeopardy by an official combination with Sir William Armstrong, which must be regarded as a gross job; and the lamentable consequences, which flowed from it, are appealed to as a justification of the disgraceful act.

(To be continued.)

MR. CULLEY'S "HANDBOOK OF PRACTICAL TELEGRAPHY."*

It is little more than a year since, on the appearance of the first part of Mr. F. C. Webb's treatise "On Electrical Accumulation and Conduction," we had occasion to notice a really valuable contribution to that science which has given to us the "wonder-working wire," and which promises in the future to do still more in the cause of civilization and material progess. Mr. Culley's work is, perhaps, equally meritorious in a different sphere. Possessing but little claim to scientific originality or profound research, it will, nevertheless, for many years to come, remain a standard work on electro-telegraphy. At the present moment it is the *only* standard work on the subject in the English language. We may refer occasionally to the works of Highton, O'Shaughnessy, Lardner, and Walker, or to the American authors, Vail, Jones, Trumbull, and Shaffner; but none of these could we confidently recommend as a guide to those who may have to qualify themselves as efficient telegraphists. It is not alone that they lack the impress of modern improvement; for the French works of Moigno and Blavier, and the German treatise of Schellen, may also be regarded as somewhat out of date, though still accepted authorities; it is that they are wanting in the well elaborated, concisely expressed technical knowledge which distinguishes the present production of Mr. Culley, and which appears, in some measure at least, to have been derived from a careful study of the French authors, Blavier and Gavarret. But Mr. Culley has also brought to bear upon his task a tolerably extended experience, and no inconsiderable amount of native ability. In many points he is simpler, more lucid, and more concise than the foreign authorities; besides possessing the great advantage—in our eyes—of writing upon the English system of telegraphy, and, therefore, from the point of view that our telegraphic learners should evidently, if possible, obtain.

The first division of the work, "On Sources of Electricity," is the most unequally written; for, though generally accurate, and admirably adapted to the requirements of the learner, it allows of some misconceptions in relation to the "tensions" obtained by the elements of a voltaic couple, and in the definition of the "intensity" of a current. We hope to see these points more fully elucidated in a second edition of the "Handbook," and we think we see some reason to advise the author to refer to the original work of M. De la Rive, rather than to the English translation, which he appears to have consulted as an authority.

* "A Handbook of Practical Telegraphy," by R. S. Culley, Telegraphic Engineer and Superintendent. Published with the sanction of the Chairman and Directors of the Electric and International Telegraph Company. London: Longman, Green, Longman, Roberts, and Green.

After giving an instructive *resumé* of facts relating to magnetism and electro-magnetism, Mr. Culley proceeds to apply the law of Ohm to the telegraphic circuit, showing how the battery arrangements should be modified according to the resistance of the line, &c. It is wonderful to observe what has been done by the application of this law, mainly expressed —so far as it relates to ordinary problems—by a very simple formula, to divest electro-telegraphy of empiricism, and to give to it the accuracy of science. It enables the telegraphist, not only to know beforehand the exact amount of battery power required to produce signals of a certain strength at the distant station, but, as Mr. Culley shows in a great number of examples, to determine with accuracy the position and extent of any "fault" in insulation upon the line. The formula in question will be found at p. 48 of the work, and should be most carefully studied by the learner, as it constitutes the *pons asinorum* over which he must necessarily pass before he can hope to become an efficient telegraphist. The law of "derived currents" (p. 75, *et. seq.*), and its practical application, are also of the utmost importance.

In regard to the materials to be used for the insulation of overland wires, Mr. Culley gives the preference to ebonite and stoneware, either alone or in combination. Glass conducts the current to earth through the moisture which collects upon the surface of the insulator; while porcelain is liable to be under or overburnt, in which cases it is either a conductor from the first, or becomes so by reason of its porosity. These hints are well worthy of careful consideration; for, perfect as the insulation of most of our English lines may be in comparison with those of America, there is still ample room for improvement in this respect.

The chapters on "Testing for Insulation and Resistance," and "Testing for Faults," are most carefully written, and are illustrated with numerical examples by which the learner will be aided in impressing upon his memory the principles upon which the tests are founded. The latter portion of the work is devoted to the description of the Morse and Bain printing telegraphs and needle instrument, and to the "Construction of a Line of Telegraph." The Appendix contains several notes of interest and value to the student, such as the methods of constructing scales for the various descriptions of galvanometer, an account of Gaugain's "Tangent Multiplier," &c.

The work extends over 190 pages, and is illustrated with numerous diagrams and drawings. It is written—as the author remarks in his preface—in a language popular rather than scientific. Although problems relating to submarine telegraphy are, for the most part, not treated upon, it fully bears out its title as a general Handbook, and will doubtless be well appreciated by a large number of practical telegraphists in this country and its dependencies. We have every reason to congratulate Mr. Culley on his first venture as a writer upon a subject he is evidently well qualified to handle; and we look forward to the publication of a secondedition of the work, at no very distant date.

PROPOSED HIGH LEVEL BRIDGES OVER THE THAMES.

(From the *Daily News.*)

When the Select Committee of the House of Lords reported in favour of a railway which should form an "outer circle" round London, with "a bridge on the eastern side of the metropolis to connect the railways north and south

of the Thames," they must have very imperfectly considered the difficulties attending such a work. Certainly they had no evidence before them to justify such recommendations. The evidence went to show the possibility and the difficulty of passing through London, and connecting the different railways within the metropolitan circle, and it also illustrated the possibility and the difficulty of using the Thames Tunnel as a means of communication from one side of the Thames to the other. No one, however, was bold enough to propose an "outer circle" railway with "a bridge" across the navigable part of the river; nor can it be supposed for a moment that the Lords themselves knew what such recommendations would involve.

First, let us take the bridge. A bridge across the Thames is, of course, the key of such a railway. Without it an outer circle railway would only work back traffic from Blackwall on the north side of the river, round by Kensington, to Rotherhithe, on the south of the river, and *vice versa*. This it is possible to do at present by the North-London and other lines with even greater facility than an "outer circle" line could effect it. A bridge at the east of London, then, is the key of the outer circle system, without which an outer circle line must fail. Now, for the benefit of the House of Lords and of the public generally, let it be considered what such a bridge implies.

"A bridge at the eastern side of the metropolis" implies a bridge on a high level, so as not to interfere with the shipping of the Thames. It was to avoid the construction of such a bridge that Sir Isambard Brunel proposed the Thames Tunnel. So far back, then, as the time of that enterprising engineer any sort of communication, however difficult to effect, was considered preferable to a bridge. One reason for this is that the high level required (not less than 150 ft. above high water mark) must be obtained from perfectly flat shores. How is this to be accomplished? Hitherto such a work has certainly never been attempted anywhere. The high level railway bridge at Newcastle—which being above the navigable part of the Tyne was not required to be on a high level for the convenience of shipping, but only for the convenience of railway communication—starts from the summit of the high cliffs through which the river flows. The Britannia-bridge across the Menai Straits also starts from banks very much elevated by nature on either shore. But in the case of the bridge across the Thames imagined by the House of Lords an artificial access to the high level must be obtained from both shores of the river, requiring the construction of a hundred bridges, on high levels, across thoroughfares, railways, canals, rivers, and even across docks, before the level of the bridge across the Thames can be approached. It is needless to point out how much the construction of such approaches must add to the expenses of the bridge itself.

But this is far from being all. The bridge must not only be on a high level, but, to admit of the free passage of shipping, it must be of a great span. The smallest span spoken of in connection with these high level bridges is a span of 800 ft. No fixed bridge has ever been attempted by the boldest engineer with any such span as 800 ft. The only bridge in the world over which railway carriages are passed, which has a span of 800 ft., is the bridge at the Falls of Niagara, constructed by Mr. Roebling, an American engineer, on the suspension principle. But the suspension principle would be utterly inapplicable to a bridge across the Thames. A suspension-bridge oscillates with the weight of the load, and with the momentum of the carriages passing over it. No load much exceeding 300 tons has ever been conveyed, at any one time, over the Niagara suspension-bridge, and no train is allowed to pass over that bridge at a greater speed than three miles an hour. Even with these limitations the span of the Niagara suspension-bridge has been thought so dangerous that it has been practically diminished to 700 ft., by building up supports at each of its extremities.

No engineer would propose a suspension-bridge for railway purposes across the Thames; and, therefore, we may take it at once that the proposed bridge would be a fixed bridge, built upon the tubular principle, or on the lattice principle, which is a modification of it. Now the central tubes of the Britannia-bridge are each 472 ft. long. The height of these tubes is 31ft.; their width 14ft. 8 in.; their weight little less than 2,000 tons. It will be remembered that a great facility presented itself to Mr. Robert Stephenson for the erection of the Britannia-bridge. In the very centre of the Menai Straits there was a rock, called the Britannia Rock, of which he took advantage to build a pier, upon which the tubes were rested. No such favourable opportunity presents itself in the channel of the Thames. There is no favouring rock in the middle of the Thames, and to build a pier or staging from the bed of the river, in the centre of the tideway, of sufficient height to carry the works over the centre of the stream 150 ft. above high water mark, may be considered an impossibility. The bridge, therefore, must have a span from shore to shore, which implies a span of 800 ft. at the very least; and in order to be in proportion to 800 ft. in length the bridge will require to be nearly 60 ft. in height and of corresponding breadth. The weight of such a bridge could not be estimated at less than 5,000 tons; and whether such a weight could stand at a span of 800 ft., or whether a bridge with such a span would not break down of its own weight, is a question which experience at present has not determined.

One thing, however, has been determined respecting such a bridge—and that is, the difficulty of setting it up. The iron tubes of the Britannia, 470 ft. in length, were floated into the Menai Straits, and with all the advantages of that position were got into their places with extreme difficulty, and were only raised to the required levels, after six or seven weeks' hard labour, with the aid of the most powerful hydraulic machines ever employed. Now let us suppose a tube, nearly double the size of those used for the Britannia-bridge, to be constructed on the Thames, it may be at Millwall; let us suppose it safely floated to the point at which the piers for the high level bridge are to be erected on either side the Thames. How is this tube, or beam, or whatever it may be, of 800 ft. in length, and nobody knows how many thousand tons weight, to be erected 150 ft. above high water mark? Can such a work be executed without stopping the navigation of the river for a period of time which may depend on a variety of contingencies and accidents? Contractors are bold men; but is there any contractor bold enough to encounter the liability which would accrue from the stoppage of the navigation of the River Thames for a month, a week, or even for a day, during the progress of an attempt to lift a tube, or a multiplicity of beams, equal in measurement to the breadth of the river itself, to a height of 150 ft. above the river level? We say nothing of liability to accident. That is supposing an extreme case. But the question is, how a bridge is to be constructed at a height in the air of 150 ft., with a span across the river of 800 ft., and without the possibility of constructing even a staging in the centre of the river to facilitate the execution of the works?

Before considering further the question of outer circle railways dependent upon bridges over the navigable portion of the Thames, it would be well to know how such bridges admit of execution.

MEETING OF ENGINEMEN IN LEEDS.

The usual half-yearly meeting of the National Engineers' Association has been held in the large room of the Central Market Hotel, Leeds. Delegates attended from most of the manufacturing towns of Yorkshire, Lancashire, and Cheshire.

At the conclusion of the ordinary financial business of the Society, Mr. Robert Rae, of Leeds, was unanimously called to the chair. A discussion took place upon the various engineering topics of the day, and the general management and economy of steam engines and steam boilers. Amongst the inventions referred to, was a patent lubricator, by Thomas Willoughby, of Leeds; a patent sludging apparatus, by Mr. Needham, of Dukinfield; and also a steam boiler on an entirely new principle, by Mr. Elson, of Oldham. By this boiler it is proposed wholly to dispense with the present huge and ponderous vessel—containing from 10 to 12 tons of boiling water, and a pent up explosive force of from 4,000 to 5,000 tons—and to substitute a series of small bottle-shaped tubes, or cylinders, of about 240 times less capacity than the ordinary steam boiler, the requisite amount of heating surface being obtained by increasing the number of these small vessels or bottles. By a peculiar arrangement these bottles or cylinders both receive their supply of feed water and discharge their steam through the top opening or bottle neck, and thus leave the bottoms entirely free and disconnected from any other part. This has proved an efficient remedy against breaking of joints, or leakages arising from expansion and contraction. The advantages proposed to be realized by this new boiler are numerous. In the first place, it is contended that loss of life from boiler explosions may thereby be entirely prevented; for in case of any one of these tubes bursting there is not sufficient explosive matter to dislodge the brickwork or destroy the building in which they are situated. 2nd. A great economy in fuel is anticipated from the circumstance of being able to keep all the heating surface clean, and free from soot, by the application of self-acting scraping gear, and also from an increased range of expansion of steam in the engine, by being able to carry much higher pressures than are attainable with the present form of boiler. 3rd. A much diminished first cost, being at least 20 per cent. less than the present cost of boilers. 4th. A great saving of space occupied; this apparatus only occupying half the room of an ordinary boiler. 5th. Being able to carry any pressure up to 200 lbs. per square inch, with far less danger and risk than with present boilers carrying 50 lbs. per square inch, these vessels having been tested up to a pressure of 1,050 lbs. per square inch. 6th. Less loss of time by repairs, as any one vessel can easily be replaced in a few hours without taking down the brickwork. 7th. No danger of pipes breaking nor leakages through expansion and contraction, as all the tubes are loose at one end, and therefore free to expand and contract independently and separately. There is one of these new boilers now at work, and it has burst through, being short of water, with a pressure of 90 lbs. on. It did not do the slightest mischief, but suddenly stopped the engine.—Mr. Shaw, of Leeds, made an interesting and practical speech, chiefly upon boilers and their mountings, cautioning enginemen against many of the dangerous practices which they themselves are sometimes guilty of, such as hanging three or four weights, and sometimes even bricks and stones or other substances upon the levers of their safety valves, and of not opening their water gauges sometimes for two or three days together, &c.—Mr. E. Ingham, of Oldham, next addressed the meeting on the necessity of enginemen becoming better acquainted with the science and theory of their profession. In conclusion, he stated that notice had been given in the House of Commons to bring in a bill next session of Parliament, with a view, if possible, to prevent the recurrence of so many of those devastating boiler explosions which they all had to lament of late. He read letters from the framer of the bill, and from the Members of Parliament for Oldham, asking for the opinions of intelligent engineers upon the bill preparatory to its introduction in the House next session. In Lancashire they had had meetings of engineers, but not yet of the masters; and the general impression seemed to be, that in preference to Government inspection it would be better to establish local Boards in every large town, composed of gentlemen in the town, and a fair proportion of the more intelligent of the working engineers, whose election and terms of office might hereaft… be determined upon. They had (he ad… carried on a system of l… mutual insp… steam boilers in Oldh… last twe…

and during that time, although they had perhaps more boilers in Oldham than in any other town in England, they had only had one fatal explosion under their Association, and that was only attended with the loss of one life.—Addresses were also delivered by Mr. Jackson, of Leeds; Mr. Williams, of Manchester; and others; and a very interesting meeting was brought to a close by a vote of thanks to the Chairman.

DEACON'S IMPROVEMENTS IN WIND-GUARDS FOR CHIMNEYS.

MESSRS. S. AND C. DEACON, of London, builders, have recently patented the following improvements in tops, caps, and windguards for chimneys:—

Hitherto, in chimney tops, caps, and windguards formed or provided with covers at top, these covers have been fixtures, and consequently resist the ascent of the brush or cleaning instrument, from which cause damage is likely to result.

The present invention, first, consists in constructing the covers of chimney tops, caps, or windguards in such manner that the covers shall open and close—that is to say, they shall be opened by the brush or ordinary cleaning instrument when it moves upwards so as to allow such brush or instrument to pass up through the top, and shall close or return to their previous position when the said brush or instrument is lowered or withdrawn.

Various arrangements may be adopted for carrying this into effect; but the patentees prefer one or other of the following modes—in the first of which they form the cover of two flaps, lids, or doors hinged or jointed to the top, cap, or windguard, and meeting together over the top of the chimney; these doors are weighted. When the brush or ordinary cleaning instrument is driven against them, they are forced open and allow the brush or instrument to pass through; and when the brush or instrument is lowered, the doors come together again, and close over the chimney top. A convenient shape for the doors or flaps is angular, recessed, or concave, the sides forming planes inclined inwards or segments curved inwards, that is, towards the part where the doors or flaps meet.

In another arrangement, the doors or flaps are weighted and are suspended or jointed to the cap, windguard, or top, by sliding pieces sliding on rods or supports, so that the doors or flaps are free to turn or swing in either direction; the brush or ordinary cleaning instrument, when driven upwards, forces them to swing or turn outwards, and so to open and allow the brush to pass through; and they work or swing in a contrary direction or inwards when the brush or cleaning instrument is lowered, and then return to their closed or original position. Instead of weights, springs may be used in either arrangement. Guards, shields, or flaps may be jointed to the chimney caps, tops, or windguards over the slots or openings in the sides, such guards, shields, or flaps being fitted and worked as hereinafter described to open and close the said slots or openings.

The invention next relates to an improved cleaning apparatus, the object of which is to clean the inside surfaces of the guards, shields, or plates fixed outside the openings or slots of windguards, chimney tops, or caps. This cleaning apparatus consists of scrapers, brushes, or other cleaning appliances fixed to a ring, band, or frame by shanks which pass out through the said slots or openings, the ring, band, or frame being within the body of the cap, windguard, or chimney top. When the usual brush or cleaning machine is pushed up against the ring, band, or frame, the latter is forced upwards, and, of course, carries with it the scrapers or other cleansing appliances attached to it, so that these rub against and clean the inside of the guards, and when they reach the top of the slots or openings, the brush clears the ring or frame, and the latter drops to its previous position, and leaves the brush free to pass upwards. Though this frame may generally be described as annular, it need not be circular, but may be square or of other required shape, and correspond to the section or inside form of the cap, windguard, or top, and lie close round it on the inside; but it must always have a space or open way through it for the brush to pass.

DEACON'S WINDGUARDS FOR CHIMNEYS.

FIG·2 FIG·3 FIG·1

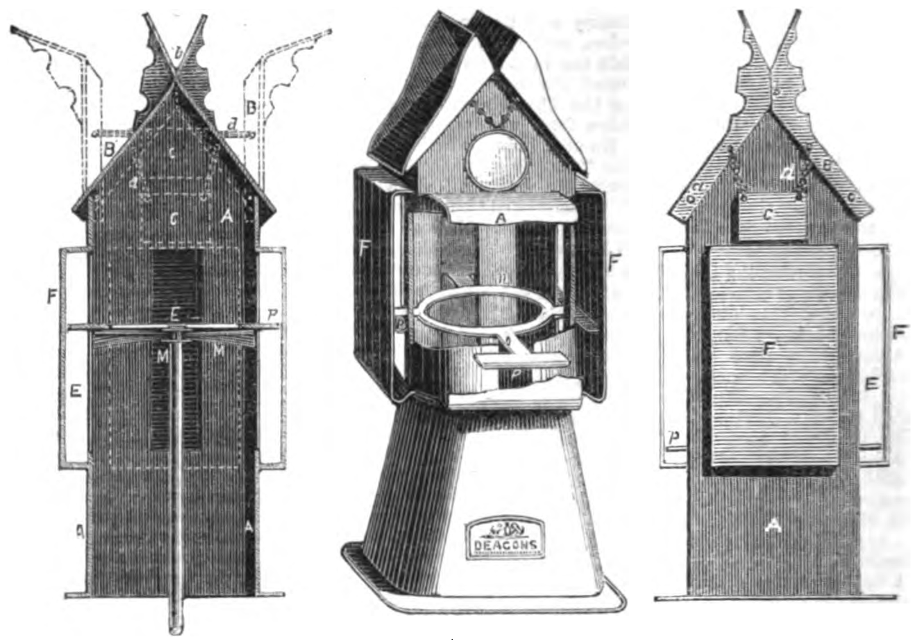

Fig. 1 is an elevation of a chimney top, cap, or windguard, having covers constructed according to this invention; and fig. 2 is a vertical section.

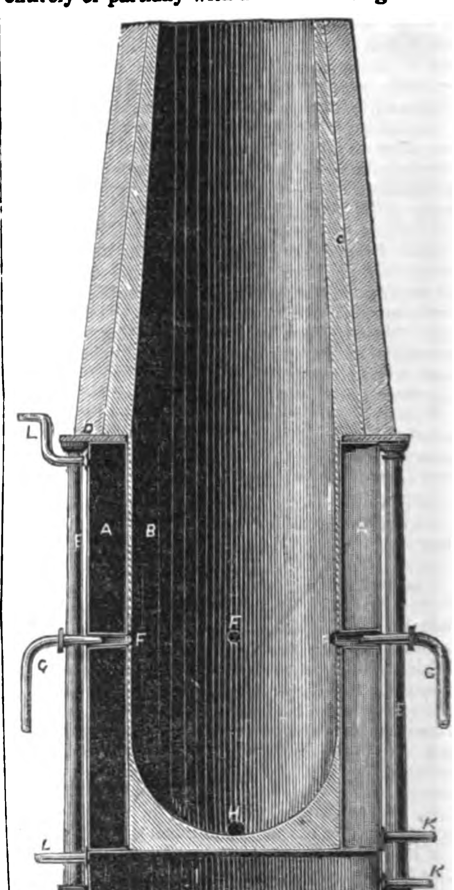
A is a top, cap, or windguard of any ordinary or desired form; B, B, is the cover, which, instead of being a fixture as heretofore, is capable of being opened and closed; it consists of two doors or flaps B, B, hinged at a to the body body of the chimney cap A, and meeting together at b; c is a weight suspended by chains d to the doors B; there is a similar weight on the opposite side. M is an ordinary brush. When the brush is pushed up, it forces the doors B open and passes freely through; when the brush is lowered and clears the doors, the latter close. Their angular shape facilitates the return of the brush.

Fig. 3 shows the improved cleaning apparatus in position within the windguard.

This apparatus consists of a ring n, on which are short shanks or projections o, having at their ends scrapers or other cleaning appliances p; the shanks o pass through the slots, wind holes, or openings F in the sides of the cap A, and the outer edges of the scrapers p extend to the guards F fixed before these openings. The ring n with its shanks and scrapers, when in the ordinary position, rests on the bottom of the guards F; and when the brush M, fig. 2, is introduced and reaches the ring n, it pushes it upwards, and the scrapers p rising with it, rub against and cleanse the inner surfaces of the guards F. When the brush has forced the ring to the top of the guards F, it clears the ring and passes through it, and the ring drops with its scrapers to its previous position at the bottom of the guards. The ring may be of any desired shape to suit the inside of the cap; and the scrapers or appliances p may be of any desired shape to suit the shape of the guards.

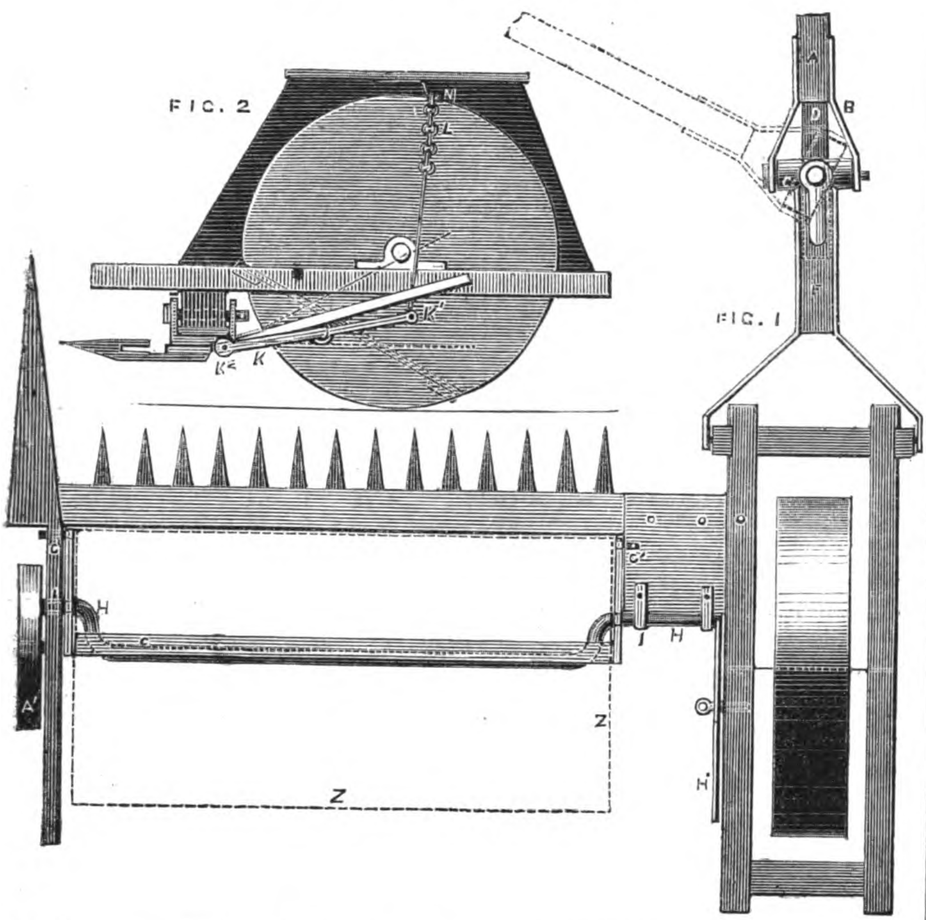
PRICE'S IMPROVEMENTS IN CUPOLAS.

THIS invention, patented by Mr. A. P. Price, of Lincoln's-inn-fields, consists in so constructing cupolas, blast furnaces, or other similar furnaces employed for the manufacture, fusion, or in the production of cast iron, steel, or other metals, and of crucibles or other similar vessels employed in the conversion or refining of cast iron in the manufacture and production of iron or steel by the injection of air or gases, or by that process known as the atmospheric process, in such a manner as that they shall be surrounded either entirely or partially with a hollow casing of cast



iron, or of malleable iron, or of other suitable metal, and shall be so constructed that a current of water, or jet of steam, or a blast of air may circulate freely through and around such hollow casing, by which means the sides of the cupola,

BAMLETT'S REAPING MACHINES.



blast furnace, crucible, or other similar converting vessel may be cooled, and the lining of the cupola, blast furnace, crucible, or other similar converting vessel may be preserved from the destructive action of the heat and the fluxes. When this casing is applied to crucibles or converting vessels used in the conversion of cast iron into steel or iron, and require to be moveable, the casing in constructed in such a manner that it shall be closed with the exception of suitable inlet and outlet pipes, so that no water, steam, or air shall escape except by such outlets when the vessel is moved for the purpose of discharging its contents. The inner surface of the casing may be lined with fire-brick or fire-clay, or any other suitable material.

A, in the engraving, is a cylindrical or other-shaped closed or open jacket of wrought or cast iron, or other suitable metal, forming, when lined with fire-clay or fire-brick B, the lower part of the cupola, blast, or smelting furnace, the jacket being, by preference, applied to that part of the furnace only where the greatest heat is generated. This jacket or casing may be formed of one or more pieces, as preferred. The furnace may be constructed and combined with the jacket in various ways. The upper part or brickwork C rests upon a stout ring or annular bed-plate D, of iron or other material, which may be itself partly supported upon the closed or open top of the jacket or casing, and partly by the outside columns E, E, or the upper part of the furnace may be entirely supported by the columns and ring or bed-plate D. F, F, are tubular openings in the jacket or casing for the reception of the nozzles of the tuyeres or blast-pipes G, G, a similar passage H being made at or near the bottom of the upper jacket or casing, or below the same, to be used as the tap hole. The base or bottom of the cupola may or may not be composed of another water-jacket I, which may be either distinct from or in one piece with the upright, or cylindrical, or other-shaped jacket or casing. In these jackets or casings a constant circulation of air, steam, or water is maintained by the inlet and outlet pipes K and L. When water is employed in a closed jacket or casing, it is preferred to bend upwards the exit pipe L, in order to ensure that the jacket or casing be constantly and perfectly full of water.

BAMLETT'S IMPROVEMENTS IN REAPING MACHINES.

THE first part of these improvements, patented by Mr. A. C. Bamlett, agricultural engineer, Ripon, Yorkshire, relates to such reaping and mowing machines as have the pole to which the horses are attached fixed to the machine by a universal joint, being designed to facilitate turning at the corners of the field and to prevent accidents, and consists in controlling the movement of the pole by means of chains or projections fixed on the pole and fore part of the frame, so as only to allow the pole to turn to about right angles with the frame of the machine or about parallel to the cutter bar.

Secondly, in order to alter the "pitch" of the ordinary platform commonly known as "Hussey's," the patentee mounts it in a frame which is jointed near the front edge of the platform. The frame is acted on by cranks, levers, or their equivalents, and by these means the pitch of the platform can be varied as required.

In the annexed drawing, fig. 1 is a plan view, and fig. 2, a side elevation of so much of a reaping machine as is required to show the mode of carrying out this invention.

A, A, is the pole, which is attached by two iron straps B and B^1 to the castor or swivelling part C, C, of the guiding wheel D. One of the iron straps B^1 has its end B^2 bent upwards, which bent part, in turning, comes in contact with the projection E (fig. 2) on the fore part of the frame F, which prevents the pole from turning any farther than is shown by the dotted lines, fig. 1, thus preventing accidents to the horses (through their feet coming on to the cutters) and making the machine easier to turn at the corners of the field, as the small wheel A^1 is pushed backwards when the horses try to turn the pole farther than is shown by the dotted lines in fig. 1.

The second part of these improvements is to readily alter the pitch of the ordinary tilting platform (commonly known as Hussey's or Dray's Hussey platform) so as the better to adapt it to long or short crops.

In figs. 1 and 2, the platform is mounted in a frame G, G, which is jointed to the machine near the front edge of the platform at G^1, G, Underneath this frame is a cranked lever H, H mounted in bearings I, I; it is capable of being raised by the lever H^1, thus altering the pitch of the platform.

A simpler method of altering the pitch o the ordinary tilting platform, and one which is easily applied to reapers that have a jointed finger bar, is shown at fig. 2. The crank lever and frame K, K, is made in one piece, which is jointed to the machine at K^2, K^2, and is held in position by a rod and chain L, L, attached to the crank lever frame at K^1 and to the hook M. By hooking the chain into different links the pitch of the platform is altered, as shown by the two single dotted lines the double dotted lines show the position of the platform when tilted, it being pivotted to the cranked lever frame as shown.

MARTIN'S NEW ANCHOR.

A NEW description of ship's anchor, invented by Mr. Martin, and ordered by the Lords Commissioners of the Admiralty (as stated) for Her Majesty's ship "Edgar," Rear Admiral Sydney Dacres, C.B., was on Saturday tested by the hydraulic machinery in Woolwich Dockyard. A number of scientific persons were present to see the working of the apparatus, for which a medal was last year awarded to Mr. Martin by the Commissioners of the International Exhibition. The weight of the anchor tested is 24 cwt. 2 qrs. 12 lbs., and that of the steadying bar 1 cwt. 2 qrs. 2 lbs. Its construction and shape in no way resemble that of any other anchor yet in use. It consists of a shank, two palmed flukes, and a sector with palms, and has no stock. Both flukes take hold of the ground at the same time, leaving no part exposed to the danger of fouling or being fouled, however shallow the soundings and anchorage may happen to be. At the test on Saturday, the tensile strain commenced at a pressure of 15 tons, which gave a deflection of one-eigth of an inch; at 20 tons of ¼ of an inch; and at 24 tons of 5-16ths of an inch, that being the required Admiralty test. The permanent set, 9 tons, gave a deflection of 3-16ths. The strain off, the anchor returned to the same point at which the pressure commenced and exhibitd no permanent deflection. The proof was pronounced thoroughly satisfactory. The anchor will be removed this morning to the smithery, and will be fire-proved—namely, heated to a low red heat, to discover if the metal is free from flaws or defects. Arrangements have been entered into to carry out the manufacture of the anchors on a large scale. For that purpose a company has been formed, of which Vice-Admiral the Hon. Sir Montague Stopford, K.C.B., is the chairman; Rear-Admiral Sir Thomas Raikes Thompson, and Rear-Admiral W. H. Hall, C.B., director of the Peninsular and Oriental Steam Navigation Company, and other influential persons, are the directors. Admiral Stopford, Mr. Martin, and various members of the company, were present at Woolwich, and witnessed the test, as also the Commodore-Superintendent, Sir F. Nicolson, C.B., Mr. Turner, master shipwright, and the principal officers of the yard.

THE SUEZ CANAL.

Advices from France state that the labours of M. Lesseps and his comrades are pursued with an activity and regularity which leave nothing to be desired, the working parties replacing each other in the cuttings without interruption. The fresh water canal rapidly advances towards Suez; and, before another year, the waters of the Nile will have been carried to the borders of the Red Sea—so at least say the engineers who conduct the works, and this with a confidence which leaves little doubt of their sincerity.

As soon as this desirable end has been accomplished, the labourers will be transferred to the more important work of excavation involved in the formation of the ship canal. One party continuing the clearing of the channel at Serapeum; another party will proceed to Port Saïd, excavating all that can be raised dry in Lakes Menzaleh and Ballah, in order to prepare the way for the steam dredges. Subsequently, M. Lesseps' little army will be wholly employed on the line from Lake Timsah to the Ameer lakes, completing that section of the canal which extends from Serapeum into the plains of Suez. In this way the waters met with in the course of the excavations will drain naturally into the Ameer lakes, in order that the greatest possible amount of work may be executed in dry cutting. The moment that matters are sufficiently advanced, MM. Duggaud Bros. will commence their labours at Port Saïd, in the construction of the necessary jetties and embankments.

The unanimous opinion of the Commissioners who have recently examined the work in all its details, is, that every portion of the canal will be completed within three years and-a-half or four years at furthest.

GREAT AMERICAN LOCOMOTIVE.

The giant anthracite coal-burning locomotive pusher, lately designed and built by Millholland, for the Philadelphia and Reading Railway, is to be used for pushing heavy coal trains between the Schuylkill river and the coal piers at Port Richmond, where there is a grade of about 34 feet to the mile for one and three-fifths miles. The following description of the dimensions of this monster pusher is from the *Railroad and Mining Register* of Philadelphia:—

Number of drivers	12
Diameter of drivers	43 inches.
Between centres of axles	3 feet 11 inches.
Wheel base	19 feet 7 inches.
Diameter of cylinder	20 inches.
Stroke of piston	26 inches.
Length of main rod	11 feet 4 inches.
Length of steam ports	18¾ inches.
Width of steam ports	1⅜ inch.
Width of exhaust ports	3¼ inches.
Lap of valve	¼ inch.
Diameter of boiler	48 inches.
Number of tubes	174
Length of tubes	13 feet 6 inches.
Diameter of tubes	2 inches.
Inside length of fire-box	9 feet.
Inside width of fire-box	42 inches.
Depth of combustion chamber	25 inches.
Total heating surface	1428 square feet.
Grate area	31¼ square feet.
Length of engine over all	36 feet.
Width of engine over all	8 feet 6 inches.
Height from rail to top of stack	14 feet.
Weight of engine	100,320 pounds.

The water tanks, three in number, are placed one on each side of fire-box beneath the foot-board, and one over top of fire-box with an aggregate capacity for 1,224 gallons. The firing, when necessary, is done at the ends of trips, no coal being carried excepting that in the fire-box. Two Giffard injectors, Nos. 9 and 10, are provided for feeding the boiler. The exhaust nozzle can be varied from 11 to 23 square inches in area. The grate bars are hollow tubes, having a circulation of water through them, James Millholland's patent. Length of grade upon which the engine operates 9,000 feet. Height per mile 34 [illegible]n *Railway Times*.

ON MAGNETO-ELECTRICITY, AND ITS APPLICATION TO LIGHTHOUSE PURPOSES.*

By F. H. Holmes, Esq.

(*Concluded from page* 866.)

Thus, then, we have a most intense light, which may be maintained for any length of time, which does not require to be trimmed or extinguished for a second, and which has all the steadiness and uniformity required for lighthouse purposes. Its advantages over the oil lamp are: first, its power can be increased *ad libitum* without increasing the size of the lens, for, if required, a machine may be made so give light enough to read by, say, at 10 or 20 miles—in fact, the light is in direct proportion to the power of the machine that produces it; secondly, its great intensity gives it a power of penetrating haze only equalled by the sun; thirdly, its whiteness distinguishes it most perfectly from all other lights on shore, which is one of its most important properties, for many a vessel has been lost for want of this property in lighthouses lighted with oil; fourthly, where coloured lights are required for the purpose of distinguishing one lighthouse from another, this light gives all the colours in a perfect manner, while the oil lamp always gives its own tinge to the colour employed; fifthly, from the facility with which this light can be extinguished in an instant, and as instantly lighted to its full power, it offers other means of distinguishing lighthouse from lighthouse which cannot be obtained with any other light. The importance of this may be understood from the fact that there are still many points around our shores that require lighthouses, but which must remain without them, till better means of distinguishing them with certainty from others in the immediate neighbourhood can be employed; for having no lighthouse is hardly worse for the navigator than having two in sight which cannot be distinguished one from the other.

An objection has been made to this light, that, being so small, it would be altogether invisible at a considerable distance; and when we merely consider that the apparent size of distant objects depends on the visual angle, there seems to be some ground for the objection; but the law of visual angles does not apply in the case of self-luminous bodies, as can be demonstrated with this piece of fine wire, which I suppose is almost invisible even with a strong light thrown on it, but now, if by passing a current of electricity through it, it is made self-luminous, it appears gradually to increase in diameter as it becomes brighter; and as a curious fact, illustrating the difference between the theorist in his study and the practical observer, a sailor who had seen the magneto-light from a great distance told me he supposed it must be at least 10 ft. in diameter. Another objection to the light is, that it is too bright; this may be an inconvenience in clear weather, but a light to be useful when most needed must be inconveniently bright in clear weather.

The last point to be considered is the cost of the magneto-electric light as compared with oil. The French Director-General of Lighthouses has made a report to his government, both as to first cost and as to cost of maintenance; both are greatly in favour of the magneto-electric light; of course in making their calculations of cost, they take the cost of an equal quantity of light in each case, that is, by oil and electricity.

I have now only to remark that this invention, if it may be called one, is purely English; Faraday commenced it when he discovered the fact that magnetism might be made to produce or induce an electric current; and although the magneto-light was first produced in Paris, it was by me; and so far from receiving assistance from any of the French *savants* in the matter, I was ridiculed by all of them for attempting what they said they could demonstrate was impossible. With regard to the regulator, which is also invented by me, there is another just invented by a Mons. Foucault, on a very different principle, but which is quite as effective, though overloaded with clockwork. His regulator has this peculiarity, it can be used in a rolling vessel, and will bear with impunity the vibrations of a steamer.

Discussion.

Mr. Lawrence suggested that Mr. Holmes should give a description of the practical arrangements of his apparatus at Dungeness lighthouse.

Mr. Holmes stated that at Dungeness, where the light had been in constant use since the 6th of June, 1862, there were in the lantern two small lenses, fixed one over the other, and two regulators to each. Only one light was shown at a time; but there were two regulators for each lens, so that an instantaneous change from one to the other could be made without extinguishing the light when fresh carbons were required. In the machine-room there were two magneto-machines, each capable of giving a powerful light, though both were in constant use. There was a distinct direct-acting steam engine attached to each machine; and there were two Cornish boilers, each capable of generating steam enough for the two engines. The material consumed at Dungeness was about 30 to 35 lbs. of coke per hour, and 5¼ in. of graphite in the regulator per hour, the price of this last being under three farthings per inch. The principal item of expense was, at present, the engineer, who had charge of the whole apparatus; but he expected that when there were several lighthouses on this principle, it would be found that one engineer would be sufficient for as many as were at present under the charge of an agent, and that none but stokers and lightkeepers would be required on the spot. The magneto-electric machines which were at Dungeness contained 120 horseshoe magnets of about 50 lbs. each, and 160 helices; but those which he now constructed contained only from 66 to 70 magnets, and from 88 to 120 helices.

The Chairman said he had listened with much pleasure to Mr. Holmes's very clear statement. He was glad to see present Dr. Gladstone, a member of the Lighthouse Commission, and he hoped that gentleman would favour the meeting with some remarks tending to illustrate this subject, which was one of national importance. It was most interesting to know that the little electric spark, not bigger than a pin's head, obtained by Faraday from the magnet not very many years ago, should have led to this development of power in the hands of an able and ingenious man like Mr. Holmes.

Mr. Summerlin referred to an invention of a somewhat similar character, by M. Berlioz, which, he believed, was superior to Mr. Holmes's apparatus. He would have been glad if Mr. Holmes had given some description of it.

Dr. Gladstone, F.R.S., said, as his name had been mentioned by the Chairman, he could not but rise to bear testimony to the able manner in which Mr. Holmes had brought forward this subject. During the existence of the Royal Commission, he had an opportunity of frequently witnessing the experiments made with this apparatus at the South Foreland. The Commissioners afterwards examined everything connected with the lighthouse system in France, where, at that time, when this brilliant light had been burning for half a year at the South Foreland, they were still making preliminary experiments, for they had not then overcome the irregularity of the current of electricity, and could not get a steady light. Since then they had advanced very rapidly, and orders had been given to place a double light of this description at Cape La Hève, near Rouen. The Dutch might perhaps be considered to have been before the French in the adoption of this system; and the Emperor of Brazil was probably before either. He did not think Mr. Holmes had exaggerated the power of this light, or the ease with which it was managed; and he was glad to be able to say this, because they knew that an inventor, justly proud of his child, was often unconciously disposed to give the best possible account of it. He was very glad to hear what Mr. Holmes had said with reference to the expense of an engineer being divided amongst several lighthouses, because that was the main difficulty. When the complexity of an instrument was increased, more skill was required in its management, and this necessarily led to expense. The great desideratum was to have a light which was capable of penetrating to great distances in misty or rainy weather, and in that respect this light was far superior to the Fresnel lamp, which was quite competent to send a light to the extreme horizon on a clear night. In a dense fog no light whatever was of any use; but a mere mist, or a shower of rain, the electric light could penetrate. There was abundant testimony that the lights at Dungeness and the South Foreland had been seen by the captains of steamers crossing from Folkestone to Boulogne, at a far greater distance than an ordinary oil lamp. Moreover, the intensity of this light could be augmented to any extent. Professor Faraday, in his reports to the Trinity House, had laid great stress upon this. All that was necessary was to double the number of magnets, and practically this was easily done, because there were duplicates of everything in such lighthouses, and in foggy

* Read before the Society of Arts, on the evening of Wednesday, December 2.

weather it was possible to bring the power of both machines to bear upon one instrument; and in that way double the intensity of light could be obtained. Then, further, supposing the fog to be so dense that no light could penetrate it, the steam engine on the premises might be employed to blow a horn or whistle, or to make some other noise which would serve as a direction to vessels. This had been pointed out by M. Regnault, Director of Lighthouses to the French Government, and was of great importance at a time when the question of fog signals was attracting so much attention.

Dr. Bachhoffner said, having been engaged in most of the patents taken out for producing the electric light, he had some little knowledge of the difficulties which had hitherto been considered almost insurmountable in producing the results which had been shown this evening. The great merit of this plan was the particular mode in which the electric light was obtained; and in this respect, as far as he had seen, M. Holmes had displayed a great amount of ingenuity. He confessed, when he first heard that Mr. Holmes had taken this matter in hand, he was very sceptical of his success; he did not believe that so much electric force could be obtained by the magneto-electric machine. The ingenuity displayed was very great, particularly in estimating the exact quantity of iron necessary for the core. Some years ago he (Dr. Bachhoffner) was engaged in some experiments on this subject, but he used iron wire instead of a hollow core. Mr. Holmes had spoken of the existence of liquid carbon between the two points, but this he (Dr. Bachhoffner) would be glad to have more evidence of. In using the electric light there was a deposit on one of the carbons, and with coke points pure graphite was produced; but he had great doubts as to the fact of liquid passing between the two points. A perfect automatic machine for regulating the position of the points was essential, and Mr. Holmes had mentioned that a spring formed part of this apparatus. He (Dr. Bachhoffner) was sorry there was any spring at all, or even clockwork. He thought a lamp might be constructed without a spring, and that would, in his opinion, make the machine perfect. The ingenuity displayed by Mr. Holmes up to this point, would, no doubt, enable him to make an improvement in this respect. With regard to the question of cost, he did not think either the oxy-hydrogen light or the electric light would ever be useful for purposes of general illumination, for in such cases the cost of the light was a most important consideration; but for lighthouse purposes this ought not to be regarded, because the matter involved the safety of human life. Nevertheless, it would be interesting to know what was the cost of this system, light for light, as compared with other methods. He congratulated the public, the seafaring portion of it in particular, upon this valuable application of electric power, which at one time he thought hardly possible of accomplishment.

Mr. Holmes said the cost of this light, compared with oil, had been gone into by M. Regnault, Director-General of Lighthouses in France, and he had calculated very fairly on the principle of light for light; and, reckoning in this way, including the expenses of alteration, taking down the large lens and putting in two smaller ones, putting up the apparatus, two steam engines complete, and the buildings to contain them, the whole of the cost was calculated at half that of an ordinary first-class lighthouse, light for light. They would quite understand the actual expense was greater than in an ordinary lighthouse; but when the quantity of light was considered, it was less by one-half, whilst the working expenses were only one-third. The light at Dungeness, he calculated, was equal in quantity to 14 of the large oil lamps with four concentric wicks. With regard to the intensity of the light, there was no form of combustion, and no chemical action which could produce a light—explosion was a different thing—beyond a certain amount of intensity. The greatest was that obtained upon lime, because the hydrogen and oxygen gases, burnt together, approached as nearly as possible to an explosion. With regard to the small size of this light, it might be argued that so small a light would become invisible at a great distance, say 30 or 40 miles. If an object 3 ft. in diameter appeared to be only an inch at the distance of a mile, what must this little point of light be at a long distance? He admitted there was something in this argument when based on the theory of the visual angle only, but it did not apply to luminous bodies. [Mr. Holmes illustrated this by showing a thin wire, which was almost invisible till rendered incandescent by a current of electricity, when its apparent diameter was greatly increased.]

The Chairman said the next duty which devolved upon him was the agreeable one of proposing a vote of thanks to Mr. Holmes for his valuable Paper. He was quite sure they had heard with satisfaction what had been stated by Dr. Gladstone, who had had opportunities of examining on a large scale the methods of illumination at present practised, and he was sure every remark from that gentleman would have great weight with those present. The power which this light possessed of penetrating to a great distance constituted its superiority to any system of lighting now in use; and it was to be borne in mind that that was dependent upon the extreme intensity of the heat evolved. It had been correctly stated by Mr. Holmes that of all the lights produced by chemical means, that of the combustion of hydrogen and oxygen gases upon a ball of lime was the most intense; but electricity was far more intense than any chemical action. By its means they could fuse the most refractory metals, and convert into vapour substances which could not be volatilized by other means. With regard to the precise condition of the carbon as it passed from point to point, there might be a difference of opinion. He thought it doubtful whether it was liquified. He could corroborate the statement of Dr. Bachhoffner as to the complete conversion of the carbon into graphite when coke was employed. Mr. Holmes was greatly to be congratulated on the manner in which he had contrived to economize the power of his currents. He had by an ingenious method detected the means of indicating the exact quantity of magnetism residual in the magnet. Another curious result which Mr. Holmes's practical experience had enabled him to effect, was the proportioning the weight of the armature to the size of the steel magnet, so as to avoid diminishing its power. This was one of the most curious results in the science of magnetism that had been produced in the course of this inquiry. An opportunity had been presented to Mr. Holmes of making experiments on a grand scale, which could not be done in the laboratory of the chemist. The practical man followed the theorist, and hence there arose a harmonious co-operation between the two in the advancement of science. He congratulated the Society upon having had so valuable a Paper brought before them.

The vote of thanks was then passed.

THE FIRST IRON-CLAD SHIP OF WAR.

In 1613, William Adams, in a letter from Japan, dated December of that year, in a mention of his voyage from Firando to Oosaka through the Inland Sea, by the Strait of Simonoseki, writes thus:—"We were two daies rowing from Firando to Facoate. About eight or tenne leagues on this side the straights of Xeminaseque we found a great towne, where there lay in a docke a juncke eight hundred or a thousand tunnes burthen, sheathed all with yron, with a guard appointed to keep her from firing and treachery. She was built in a very homely fashion much like that which describeth Noah's arke unto us. The naturals told us that she served to transport soulders to any of the Islands if rebellion or warre should happen."

PHOTOSCULPTURE.

REFERENCES from time to time have appeared in the papers respecting this novel application of photography. Preparations are being made in Paris for carrying it out on a very extensive scale. The results are stated to be very successful. The *modus operandi* will be easily understood. The sitter or object to be sculptured is placed in the centre of a well-lighted, spacious apartment; twenty-four or even a larger number of cameras are ranged in a circle around him, at equal distances from each other, with plates duly prepared, and by a simple mechanical arrangement the operator, by one movement of the hand, simultaneously uncovers all the lenses, and after a sufficient length of exposure closes them. The plates are then developed in the usual manner, a sufficient number of operations being employed for the purpose, and proofs are subsequently printed. There are thus obtained twenty-four or more views of the subject from twenty-four or more different points of sight. Each view is then in succession, by means of a magic lantern arrangement, thrown upon a screen on an enlarged scale. In order to transfer these likenesses from the photographs to the modelling clay, an instrument on the principle of the pentagraph is then made use of, having a tracer at one end and a cutting tool at the other. The lump of modelling clay is fixed on a stand capable of turning on its axis, with divisions corresponding to the number of photographs employed, and is placed in a position so that while the tracer of the pentagraph passes over the outline of the photograph thrown on the screen, the cutting tool at the other end cuts the clay into the corresponding outline. The clay is then shifted one division on its axis, and the next corresponding photograph thrown on the screen, and the operation repeated, and so on in succession till the clay has the twenty-four or more outlines accurately transferred to it. It then only remains for the artist to connect these tracings or outlines on the clay, and here, of course, his skill is shown. The artist thus has a large amount of work mechanically and rapidly prepared for him, and he is enabled, in a comparatively short time, to execute a model combining all the truthfulness of mechanism and the skill of the artist. From this model casts in plaster, or statues in marble, can be taken in the usual way. It is stated that the sculptures thus produced are remarkably good, and can be supplied at a very cheap rate, as compared with sculpture produced entirely by hand.—*Journal of the Society of Arts.*

THE LAUNCH OF THE "MINOTAUR."

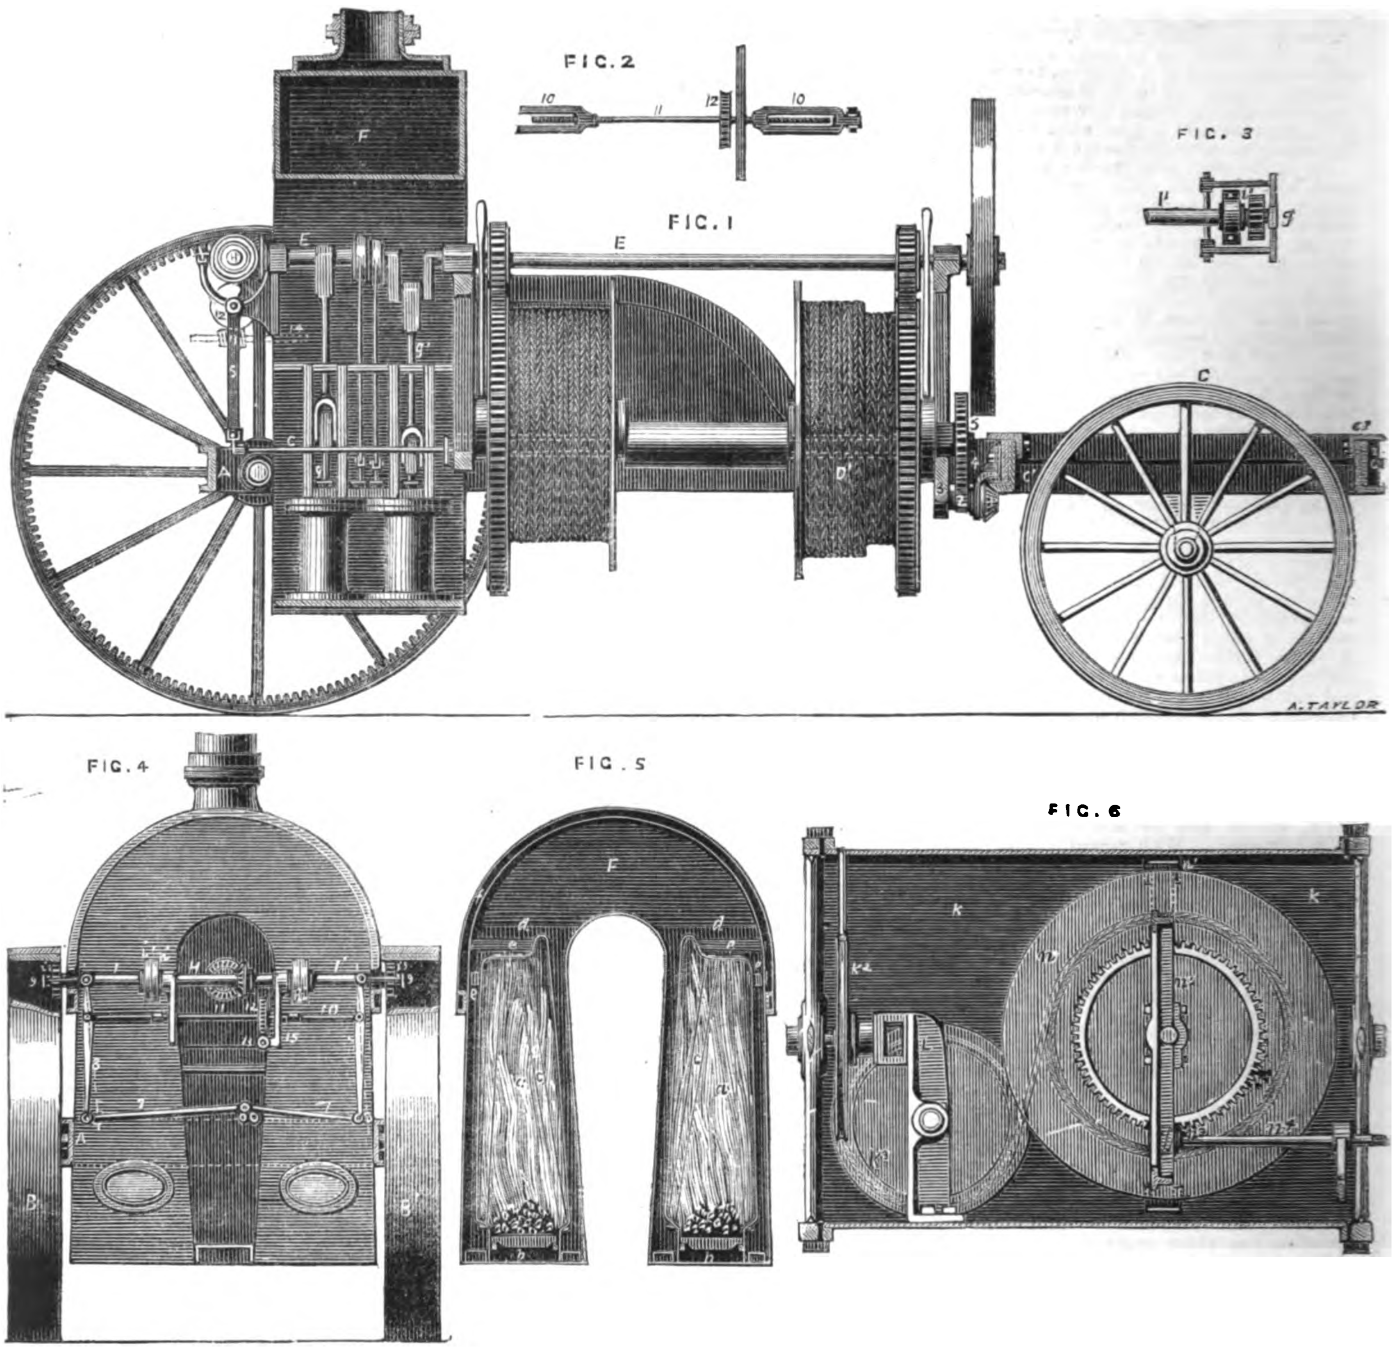
By the launch of the "Minotaur" on Saturday, our iron-clad fleet has received an important addition. This vessel, built at the yard of the Thames Shipbuilding Company at Blackwall, is the first of the largest class of armour-plated vessels, and so far as workmanship is concerned probably the most perfect of any yet afloat. Her tonnage is 6,812, builders' measurement, or 636 tons more than the "Warrior," built by the same firm. According to contract, the "Minotaur" should have been completed last May. For the delay, it is said, the Admiralty are directly to blame. Many alterations were ordered too, from time to time, which, we trust, time and experience will demonstrate to be improvements. The most important alteration was made in constructing an entirely double bottom to the ship upon the cellular system, somewhat like that of the "Great Eastern." In spite of these delays, however, considering the large size of the "Minotaur," no ship in the fleet has ever been built in so short a time; and she is a much more finished ship than the "Warrior" was at her launch. The whole of the teak backing is fastened on to her sides, and the greater part of the armour plates are fixed. The whole of the strong internal works, too, such as the compartments and the immensely strong-plated bulkheads and decks, are substantially complete.

The "Minotaur" is to have engines made by Messrs. Penn of 1,350 nominal horse power, that is, 100 higher than the "Warrior" class; and it is expected, with these superb engines, she will have a speed of at least 14 knots. The form of the "Minotaur" is very different from the "Warrior"; she is not wall-sided at any part of her lines, and when the view is taken from her bows, where she tapers finely and gradually up to her stem and swells again towards her bulwarks, nothing can be more perfect than the curves of her sides, and we should say she has the appearance of a very fast ship if her engines give her the power. The stem is made to bulge out and then in again, in the line of a swan's breast, but in form sharp as a cleaver comparatively speaking. This projecting prow is supported inside by a complicated system of cellular supports and bars, interlacing and extending back into the broader part of the ship, so as to give immense strength to this prow. Her armament will consist of 50 heavy guns, though, of course, not all 600-pounders, otherwise her armament alone would weigh above 1,000 tons, which, added to her armour which is 1,850 tons (and the weight of the empty hull is nearly 6,000 tons), would leave little for engines, rigging and masts, coal, ammunition, stores, &c. The total weight of the ship fully equipped is estimated at 10,000 tons. The following are the dimensions of the new first-rate:—

	ft.	in.
Length between perpendiculars	400	0
Breadth	59	4
Depth in hold	41	7

The launching of this immense vessel was a matter involving no small amount of practical skill and clever arrangement; yet it was accomplished with perfect ease, without a mishap of any kind. About three o'clock the last support was knocked away, Mrs. Romaine dashed a bottle of wine on the bows, named her the "Minotaur," and the mighty mass glided gracefully down the well-greased ways. Four steamers awaited her, and took her in tow, almost as soon as she was fairly afloat, towards a buoy moored below Blackwall pier. From thence she proceeds to the Victoria Docks, where the remainder of her armour will be put on, and she [illegible] her [illegible]

HOWARD, BOUSFIELD, AND PINNEY'S STEAM TILLING APPARATUS.



HOWARD, BOUSFIELD, AND PINNEY'S IMPROVEMENTS IN STEAM TILLING APPARATUS.

This invention, patented by Mr. James Howard, E. T. Bousfield, and John Pinney, engineers, Bedford, relates, firstly, to a novel arrangement of steam engine for setting in action ploughs or other implements by means of traction ropes, for the purpose of cultivating the soil.

Fig. 1, in the accompanying engravings, represents in longitudinal section the engine forming the subject of the first part of this invention; and fig. 4 is an end elevation of the same.

A, A, is the engine frame, carried by a pair of driving wheels B, B, and a steering wheel C. Upon the frame A, the barrels D,D, for carrying the traction ropes, are mounted. These barrels are driven by gearing direct from the crank shaft E, whic[h] ...tt runs longitudinally of the engine fram[e] ...passes through a divided [b]oiler F, F, s... [r]ear end of the framing, and by adopting the contrivance of eccentrics, on the axis for dropping the barrels they can be thrown in and out of gear at pleasure.

The boiler is of a vertical tubular construction, and is made of a horse-shoe or divided form to allow of the steam cylinders being placed within its lines. The two limbs or divisions of the boiler are constructed alike, as shown in the sectional elevation, fig. 5. Each part may consist of a cylindrical, or, as shown, of a rectangular tapering fire-box, the lower part of which is contracted laterally and forms the furnace. This contraction in width allows of lines of vertical water tubes, or a circle of vertical tubes *c*, *c*, being used, which pass through the fire-box and open at both ends into the water space *d*, *d*; these tubes are made slightly tapering to facilitate the circulation of the water in the boiler. To ensure the flame and heated gases circulating round the water tubes, horizontal tubular flues *e*, *e*, are introduced into the top of the fire-box. These tubes lead off the gases to the smoke-box *f*, which is an arched chamber extending from one division or limb of the boiler to the other. The steam spaces of the two divisions of the boiler are also connected together by an arched chamber, and the steam is superheated by surrounding gases on their passage to the chimney. By arranging the water tubes as explained, the sediment will fall on to the floor of the boiler, and may be readily removed through adjacent manholes. The steam is led off in any convenient way from the boiler to the cylinders G, G, which occupy the space, as before said, between the limbs or divisions of the boiler.

For making the engine self-propelling, a mitre or bevel wheel keyed on the rear end of the crank shaft gears into and drives a similar wheel keyed on a short transverse shaft H, mounted on brackets at the back of the boiler. To the extremities of this shaft friction discs or couplings are attached, such discs having, by pro-

HOWARD, BOUSFIELD, AND PINNEY'S STEAM TILLING APPARATUS.

Fig. 7.

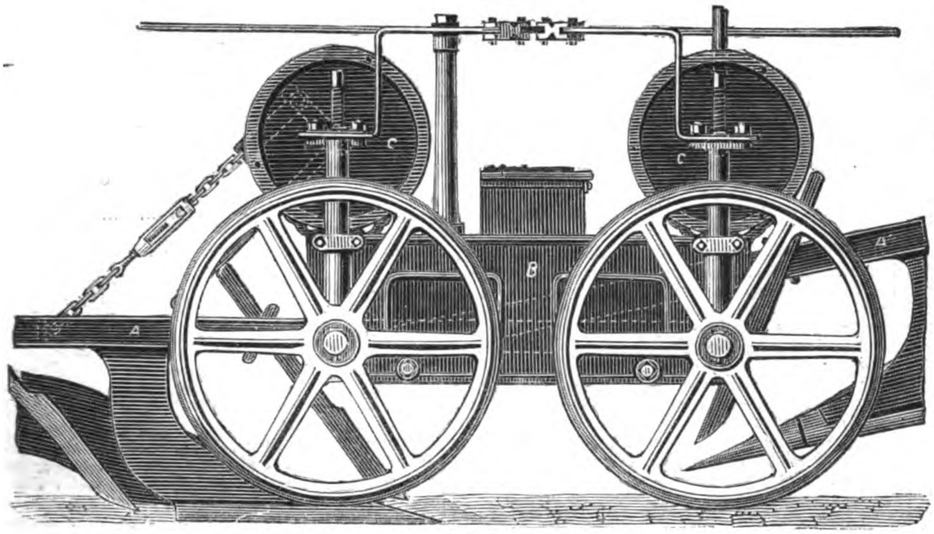


Fig. 8.

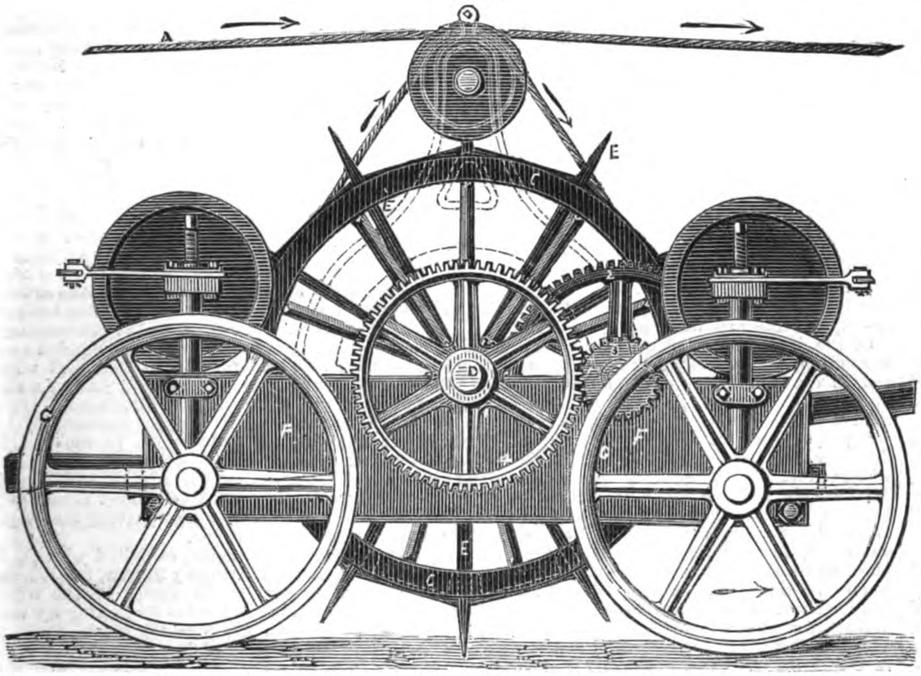

ference, annular V-shaped projections on their face. In a line with shaft this are two shafts I, I¹, carrying friction discs i, i^1, corresponding with the discs h, h^1, for establishing a connection between them and the central driven transverse shaft H. The shafts I, I¹, have an endway motion in their bearings, and they carry at their outer extremities pinions for gearing into rings of teeth on the hind carrying wheels B, B¹; or pitch chains, or other suitable modes of driving, may be employed. The natural tendency of the friction couplings will be to keep out of action, but by means of a right and left-handed screw operated by a worm and worm wheel, the shafts are pressed inwards when the carrying wheels are required to be driven, and thus through the friction couplings rotary motion is communicated from the crank shaft to the pinions in gear with the carrying wheels. This mode of actuating the driving wheels allows of their action being readily controlled by the front or steering wheel, which is operated through a segment rack and pinion or otherwise by the attendant. This rack is so coupled with the sliding shafts at the rear of the engine as by its movement to throw one or other out of action, according to the direction given to the steering wheel, by which means one of the driving wheels will remain quiescent, while the other, continuing to be driven as before, will move the engine round, the quiescent wheel being the fulcrum of the movement.

We will now describe the manner of giving an endway motion to the shafts I and I¹; and for this purpose it will be convenient first to describe the mounting of the steering wheel C. This wheel has its bearings in brackets pendent from a ring C¹ (fig. 1), which is connected to the main framing A by being embraced by the outer and inner rings C², C³, the outer ring being bolted securely to the framing. A segment rack is provided on the under side of the ring C¹, and into it gears a pinion 1 keyed to a short shaft, to which is also keyed a pinion 2. This short shaft is carried by pendent brackets. The pinion gears into a spur wheel 4, keyed to a central longitudinal shaft, which extends rearwards to the boiler, and which is coupled by gear wheels with a crank shaft 6. The cranked end of this shaft is coupled by connecting rods 7, 7, (see fig. 4), with rock levers, which extend upwards to the shafts I, I¹, respectively, and carry at their extremities a kind of saddle-piece. These saddle-pieces embrace the outer ends of the shaft, as shown best in the detached view, fig. 4, which represents the end of one shaft with its saddle-piece in plan view. To each rock lever 8 is jointed a link 10 (see the detached view, fig. 5), the inner ends of which links are tapped to receive the tapped ends of a right and left-handed horizontal screw shaft 11, by which means the two rock levers are coupled together. Keyed to the screw shaft is a worm wheel into which gears a worm carried by a shaft (see fig. 1), having a bearing in one of the brackets which support the screw shaft.

From the above description it will be understood that by turning the worm in one direction pressure may be put on the ends of the shafts I and I¹ simultaneously, and the friction discs will be coupled together, whereby a traverse motion may be given to the wheels B, B¹. If, however, the attendant turns the worm in the opposite direction he will remove the endway pressure on the shafts I, I¹, and allow the discs to be disengaged. When the apparatus is thus arranged it is ready to be acted upon by the movements of the steering wheel, thereby throwing one driving wheel into gear and the other out of gear. The steering wheel may itself be operated by the attendant through a hand lever working a pinion in gear with the segment rack on the ring C¹, and when thus operated the motion will be conveyed through the pinions 1, 2, and 4 to the the longitudinal shaft 5, thence to the crank shaft 6, and so to the rock levers 8, which rocking on the link pins as their fulcrums will throw one friction disc shaft into action, leaving the other out of action. When draught shafts are fitted to the engine for the purpose of attaching a horse thereto, the worm and worm wheel actuated by the attendant are dispensed with, the steering being then effected by the movement of the horse.

The above-described steering arrangement may be advantageously applied to road or traction engines generally.

As an improvement in the hauling apparatus for tilling land, the patentees propose, instead of employing two barrels, as above mentioned, for carrying the ropes, to use in some cases a hollow drum for carrying so much of the rope as is to be given off or taken on to produce the traverse of the implement in use, and to mount within the drum a barrel for receiving that portion of the length of the rope which is intended to be given out prior to setting the apparatus in action.

Fig. 6 is a longitudinal section of such a hollow drum fitted at its ends with spur wheels, the radial arms of which carry the trunnions for supporting the drum. Within the drum are mounted sheaves k, k^1, and k^2, supported by the framing l, which is bolted to the drum. These sheaves are for guiding the traction rope m to and from the barrel n, to which one end of the rope is secured. This barrel is mounted in frames n^1 bolted to the inner periphery of the drum. To allow of the rope entering and leaving the interior, a segment slot is cut in the drum, as shown in fig. 6. On the axle of the barrel n is a worm wheel, into which works a worm, carried by a shaft. This shaft extends through the end of the drum, and is squared at its outer extremity to receive a key for rotating the shaft and worm, and thereby moving round the barrel n when required. The normal state of this internal barrel is to be locked, which is effectually done by the interlocking of the worm and worm wheel. One end of the rope being fixed to the periphery of the drum K, a portion equal to the length of traverse of the tilling implement is wound upon the drum when the apparatus is to be brought into action; another portion is passed round the field; and the remainder through the opening made in the periphery of the drum to the barrel n, it being guided by the sheaves on to the inner barrel and wound thereon. When this windlass is first brought on to the field, it is necessary, in order to attach the rope to the cultivating implement and pass it round the anchors, to run off the required length of rope from the inner barrel, the portion of rope on the drum being used for the purpose of giving out in compensation for

the portion of rope which it winds on while effecting the traverse of the implement. For taking up any slack, the inner barrel is rotated by the attendant, who, by reversing the motion, can run out any required amount of rope to suit the dimensions of the field under cultivation.

This invention also relates to certain improvements in the ploughs or tilling implements to be used in steam cultivation. Instead of connecting the two sets of frames of double-action ploughs as heretofore by means of tie rods, chains, or springs, the patentees arrange these frames so that each set of tilling instruments is raised out of work or lowered into work independently of the other.

Fig. 7 represents in side elevation a portion of a double-action plough constructed according to this part of the invention.

A, A1, are the rocking frames, to which are affixed the two sets of ploughs, which act alternately upon the land and are alternately lifted out of the ground at the completion of a "bout." B, B, is the plough carriage, upon which are fixed two pairs of spring boxes C, C. Each of these boxes contains a coiled spring D, one end of which is secured to the fixed box, and the other to a disc E contained in the box and keyed fast to a cross shaft F. The spring boxes are connected in pairs by means of the cross shafts F, to which are affixed lever arms G, G, and a hand lever H. The frames are permanently connected to their respective spring boxes by means of coupling chains I, the ends of which are secured respectively to the rocking frames, and through cranked links to the arms G, G. The object of the springs is to give the cross shafts a tendency to rotate and wind up the coupling chains I, I, and thus to assist in hoisting the ploughs clear of the ground at the completion of a "bout." Suppose, now, the set of ploughs attached to the frame A to have completed a "bout," the attendant who has been riding upon the depressed plough frame leaves his seat, and, by lifting the extremity of the frame, is enabled, with the assistance of the coiled springs, easily to raise the set of ploughs clear of the ground. By the mode adopted of coupling the chains to the rocking shaft the raised ploughs will be effectually locked in the raised position, and will have no tendency to fall until the attendant pulls over the hand lever H and throws the lever arms G, G, over their dead centre. To prevent the raised ploughs from falling by reason of a sudden shock (produced by the implement working in very rough ground) check chains K, K, pendent from the shafts F, are provided, which are or may be hooked to the suspended frame.

Another improvement in double-action ploughs and other implements relates to the adaptation thereto of the light or fly-rope system. To this end the patentees apply a second motion shaft to, or connect the same with, the steam engine intended to be used for driving the implements, and mount thereon a grooved pulley, round which the endless hemp or light rope passes to a corresponding grooved pulley on the frame of the implement to which the power is to be transmitted. This second motion shaft is intended to increase the speed of the fly rope, and thus impart a proper speed to the implement.

Fig. 8 shows a tilling implement fitted to receive the fly rope and be driven thereby.

A is the fly rope; B the grooved pulley round which it passes to a large pulley C, running loosely on the shaft D of the propelling wheel E. This propelling wheel is fitted at its periphery with blades which bite the ground, and by the revolution of the wheel in either direction ensure a forward or backward motion, as the case may be, to the implement. The plough carriage F is supported by carrying wheels G, and the shaft D of the propelling wheels is mounted in the middle of the carriage. The revolution of the pulley C is transmitted to the propelling wheel by the following arrangement of spur gearing:—Affixed to the pulley C is a pinion 1, which gears into a spur wheel 2, on the shaft of which is keyed a pinion 3. This pinion gears into a spur wheel 4, on the axle of the propelling wheel, and thus the rapid motion derived from the fly rope is reduced in its transmission to the propelling wheel to such an extent as will ensure the requisite speed of traverse to the implement. The engine may either be stationary, and the ropes passed around the field by means of pulleys and anchors, or the engine may advance on the headland opposite to the work, the rope passing only across the field in a line with the work itself. The slack of the endless rope may be taken up by a weighted roller.

ON THE LOCOMOTIVE ENGINES IN THE INTERNATIONAL EXHIBITION OF 1862.*

By D. K. CLARK, C.E.

THE collection of locomotive engines shown in the International Exhibition of 1862 may be adopted as a fair average exponent of the best and most recent practice both English and foreign, particularly the former. The English engines were mainly examples of the standard classes in general use on the principal English railways. The foreign locomotives showed greater variety, boldness, and originality of design, and were mainly constructed for lines with very heavy gradients and sharp curves, which are generally associated together in mountainous districts, causing special mechanical difficulties not applying to the general circumstances of the English railways.

Twenty engines altogether were exhibited, of which eleven were contributed from the United Kingdom, three from France, one from Belgium, two from Austria, one from Prussia, one from Saxony, and one from Italy. Of the above twenty engines, fourteen had outside cylinders, and six had inside cylinders; and of the eleven English engines, seven had outside cylinders and four had inside cylinders. Most of the engines were specially constructed for burning coal: a feature which has been introduced entirely since the former Exhibition of 1851, on account of the smaller cost of coal for fuel compared with coke.

English Locomotives.—Amongst the English locomotives may be noticed first, as specimens of the largest class of express engines, two exhibited and manufactured by the London and North-Western Railway, one with inside and the other with outside cylinders, but both with 7 ft. 6 in. driving wheels, and designed with special regard to the running of the express trains on that line.

Of the inside cylinder class only three engines were made, as it was found to be heavy on the road and in consumption of fuel. It is an engine of maximum dimensions, and indeed must be considered beyond the capacity of the narrow gauge for proper working. With cylinders of 18 in. diameter and a stroke of 24 in., 7 ft. 6 in. driving wheels, and 26 square feet of grate, it weighs 34½ tons in working order, of which there are 14½ tons on the single pair of driving wheels. With the tender, weighing 25 tons with fuel and water, the total weight to be moved amounts to about 60 tons, exclusive of the train. The boiler has been designed for burning coal, with a combustion chamber and a double compartment of the fire-box for alternate firing, to which have been added fire-brick arches inside and deflecting plates in the doorways. The grate is 7 ft. long in two parallel strips, and the enormous amount of 242 square feet of heating surface has thus been attained in the fire-box and the combustion chamber; making the "direct" heating surface greater than has before been attained on the narrow gauge. But the advantage of "direct" surface, or that which is exposed to the radiant heat of the fire, depends upon its being within a reasonable distance of the grate; whereas in this fire-box the crown is 6 ft. 3 in. above the grate, and the upper portions of the surface are therefore nearly ineffective for evaporation. This great extension of fire-box and combustion chamber has led to the curtailment of the tubes to 9 ft. 4 in. length, and it has been attempted to compensate for this by packing 214 tubes together at ·50 in. distance apart, making 980 square feet of heating surface in the tubes. The opinion has been extensively held that heating surface is mechanically the equivalent of evaporating power, but this in the writer's opinion has not been confirmed by practice; for besides surface, circulation is wanted; the circulation of the water to the tubes, and of the steam from amongst them: and in this particular engine the evaporative power of a smaller number of tubes placed at ·75 in. apart would have been greater than that of the tubes as they are. The driving and leading springs are connected by a compensating beam, which seems likely to give an unsafe freedom of action to the engine at high speeds.

The outside cylinder engine, exhibited by the London and North-Western Railway, is one of a numerous class running the express trains on that line, and contrasts in several respects with the inside cylinder engine. It weighs only 27 tons in working order, and the tender 17½ tons, making a total of 44½ tons, as against 60 tons for the other engine; and the weight on the driving wheels is only 11½ tons instead of 14½ tons. The weights on the several wheels are—

	Inside cylinder engine.		Outside cylinder engine.	
Leading wheels...	11·90 tons	...	... 9·40	tons.
Driving wheels ...	11·30 ,,	...	... 11·50	,,
Trailing wheels...	18·50 ,,	...	... 6·10	,,
Total weight	34·70 ,,	...	... 27·00	,,

The fire-box is of the ordinary form, with little more than half the grate surface of the other engine; and it is fitted for coal burning with a fire-brick arch and two air openings in front, closed by a regulating flap. The heating surface of the fire-box is 85 square feet, being little more than one-third that of the inside cylinder engine; and there are fewer tubes, but then they are ·62 in. apart. The other engine gains the advantage in the greater size of blast orifice, which is 5¼ in. diameter for the inside cylinder engine, and 4½ in. for the outside cylinder engine; owing to the larger area of grate in the former engine, which does not require the same sharpness of blast to draw the air through.

Regarding the engines as carriages, the height of the centre of the boiler in the inside cylinder engine, 7 ft. 5½ in. above the level of the rails, is considerable, and tells upon the rails when the engine sways. In the outside cylinder engine, though the driving wheels are as large, the centre of the boiler is 11 in. lower; and this in connection with a compact wheel base and a balanced driving wheel, produces a safe, steady, and easy-running engine. In both the engines feed-pumps are displaced by two Giffard's injectors.

The outside cylinder engine is fitted with a duplex direct-action safety valve, in which a pair of valves are pressed down by a cross-bar with a spiral spring attached to the bar midway between the two valves—a decidedly superior arrangement to the ordinary weighted lever, since this valve cannot be tampered with, and is much more prompt in discharging an excess of steam, as it opens wider for a given excess of pressure. The smoke-box is furnished with a descending hopper at the bottom, having a small opening not closed, through which ashes and ignited cinders are allowed to escape constantly; thus overheating of the smoke-box is prevented. The reversing gear is worked by a screw and hand-wheel, instead of the usual long lever and notched sector; this reversing gear, which is applied to nearly 200 engines, is more easily worked, saving the engine-man a great deal of fatigue.

The tender of this engine, exhibited with it, has six wheels, and weighs empty 9½ tons, full 17½ tons, the load being equally distributed on the wheels. It is fitted with the apparatus for picking up water whilst running—a scoop is let down from the bottom of the tender, and dips into the water contained in a long open trough between the rails, from which it is made to flow up the scoop into the tender tank by the motion of the tender in running. A minimum speed of more than 15 miles per hour is required for this operation. Three of these water troughs have now been laid down and are in use in different situations on the London and North-Western Railway; and their advantages are that the size and weight of the tender for running a given distance may be reduced, the number of stoppages lessened, and time saved. An express engine has thus been enabled to run the whole distance from Holyhead to Stafford, 130½ miles, in one continuous run, without a single stoppage, at an average speed of 54½ miles per hour.

The next engine to be noticed is a passenger express engine, for the South-Eastern Railway of Portugal, 5 ft. 5¾ in. gauge, exhibited and manufactured by Messrs. Beyer Peacock and Co., whose design is characterized by elegance, thoroughness, and finish, in form, arrangement, and detail. This engine is a type of the prevalent style of English inside cylinder express engines. The framing is composed of two pairs of longitudinal bars or slabs running straight from end to end, cross-braced by the cylinders, the footplate, and various cross plates. The extension alongside the fire-box of the two inside longitudinal slabs, which stopped short in front of it in the earlier examples of this description of frame, is a great improvement

* Read before the Association of Mechanical Engineers.

in practice, as it connects the steam cylinders, driving axle, and drawplate, directly and immoveably together, and bears the entire strain of the steam in the cylinders, and transmits the tractive force to the train. The boiler is thus relieved of all strain from the working parts, from which formerly it was not free, and then suffered accordingly. The driving axle is made with only two bearings, inside the wheels, for which the guards are forged on the inside frame plate, and the leading and trailing wheels have their bearings outside the wheels; an arrangement originated by the late Mr. John Gray, and now generally adopted for its simplicity, and for the greater firmness of the frame and the increased duration of the crank axle. The steam strain is, in fact, confined to the two inside frame plates, and to the inside bearings of the crank axle, close to the cranks. The leading and trailing wheels are 3 ft. 9 in. diameter, the driving wheels being 7 ft.: the leading wheels have been thought rather too small, and no doubt there is space in the engine for enlarging them; but they would have departed from uniformity with the six tender wheels, which also are 3 ft. 9 in. diameter.

The short cast-iron blast-pipe reaching just above the level of the upper row of the tubes is to be remarked. This level of blast orifice has been found to give the best results, creating a better draught with a wider orifice, as compared with higher blast pipes; and was arrived at by Mr. Peacock, by means of a series of well arranged experiments on the Manchester, Sheffield, and Lincolnshire Railway: the low blast-pipe is now generally employed. The early blast-pipes were carried some distance into the chimney, and had very contracted orifices, and a sharp blast with much back pressure on the piston was the consequence.

The boiler, in consequence of the greater width of the Portuguese gauge, 5 ft. 5¼ in., has a large square fire-box, 4 ft. 10 in. each way over the outside shell, and has a large diameter of barrel, 4 ft. 2 in., which gives abundance of steam and water space. Nevertheless, for effective heating surface, a fire-box of oblong form would, in the writer's opinion, be better. There are 215 tubes of 2 in. diameter placed at ·56 in. apart: had the tubes been only 1⅞ in. diameter, which, upon the whole, the writer considers the best size, and placed in the same position, the larger clearance of ·69 in. so obtained for circulation, would have improved the evaporative efficiency. The fire-box is adapted for coal burning with a fire-brick arch, a deflector plate from the doorway, and sliding fire-doors, on the plan in use on the Midland Railway.

A passenger express engine for the Caledonian Railway, exhibited and manufactured by Messrs. Neilson and Co., is a specimen of the class of engines extensively used on that line, which were designed with a view to economy rather than speed, although a very large driving wheel is used; they are employed on main line service between Glasgow and Carlisle, taking their turn with all trians, fast and ordinary. From the experience that had previously been acquired of the durability and general economy of the 7 ft. driving wheels over the original 6 ft. wheel passenger engines of the line, it was supposed that a further extension of the principle of enlarging the driving wheel would be advantageous; and the extreme size of 8 ft. 2in. diameter has been adopted for trial in the class of engines exhibited: but it may be questioned whether this has not been carried too far. The cylinders are 17¼ in. diameter and 24 in. stroke. This engine has grown out of the old Crewe pattern of engine, originally introduced on the Caledonian line by the late Mr. Locke, the chief engineer, and successively modified to meet the growing requirements of the traffic. The engine weighs in working order 30¾ tons, of which the driving weight amounts to 14½ tons. This driving weight is considerably in excess of any other among the engines exhibited, except that of the North-Western inside cylinder engine; but no doubt the large size of the driving wheels, 8 ft. 2 in. diameter, reduces in some degree the injurious effects of so great a concentrated load on the permanent way. The counterweights are compactly forged into the rims of the wheels, extending over one-third of the circumference; and though a little more weight is thus requisite to complete the balance, it sweeps gently over the rails when the engine is in motion, without the sledge-hammer effect of a revolving cubical mass compressed into the space between two or three spokes. For such a large wheel also the spokes are planted thickly, at 10 in. centre to centre on the rim: the stiffness of a spoke decreases in a rapid proportion with its length, diminishing as the cube of the length, so that a spoke of an 8 ft. wheel will be only about half as stiff as a spoke of the same scantling for a 7 ft. wheel. The driving axle is of cast steel, and the tyres are of Krupp's steel.

The framing of the old Crewe engine is retained in this one, giving outside bearings to the fore and hind axles, and inside bearings to the driving axle.

In this respect, the North-Western outside cylinder engine, already described, is at variance with the older practice, having but one longitudinal frame-plate on each side, with inside bearings for all the wheels. It may very properly become a question whether the cylinders should be so rigidly united as they are in the Caledonian engine to the outside frame-plates, which carry two pairs of wheels and axles, and, of course, transmit the shocks of the road to the cylinders. The foot-plate is provided with a housing for the engineman and stoker—a most important provision for their comfort, and, consequently, for the safety of railway trains. Plain-fence plates or weatherboards across the back of the fire-box are now commonly applied to engines, and these are useful; but the housing is certainly better, and it seems strange that the adoption of so desirable a protection should have been so long neglected.

The slide valves are made with 1⅛ in. lap at each end, according to the proportion originally arrived at by Mr. Sinclair on the Caledonian Railway, from finding the peculiar importance of long lap and long travel for the valves of outside cylinders. The long lap and long travel of the valves, unquestionably facilitate the free exhaust of the steam at high speeds from exposed cylinders, in which the steam is more or less partially condensed: and moist steam being not so active as dry steam, exerts an excessive back pressure on the piston, if not freely discharged.

The boiler is fitted with the fire-brick arch and door deflector previously referred to for burning coal; the barrel is 3 ft. 10 in. diameter, and contains 192 tubes of 1⅞ in. diameter, placed with ·62 in. clearance between them. Giffard's injectors are employed. The consumption of coal by these engines is stated to average 23 lbs. per mile, with trains of nine heavy carriages and a speed of 35 to 40 miles an hour; and they take fourteen loaded carriages up the Beattock incline, an average rise of 1 in 78 for 10 miles, at a speed of 30 miles an hour.

The goods engine for the London, Chatham and Dover Railway, exhibited and manufactured by Messrs. Sharp, Stewart, and Co., is a first-rate six-coupled-wheel engine, with 5 ft. wheels and 17 in. cylinders of maximum power, adapted for the heavy loads, heavy gradients, and the high speeds ultimately intended on that line. It is a fine engine, of excellent workmanship and proportions. It weighs empty 28¼ tons, full 32 tons; and the weight is nearly equally distributed over the three axles, to the advantage of the permanent way, so that the load on any one axle does not vary more than ¾ ton from the average load on all the axles, the loads being as follows:—

Leading wheels	10·65 tons.
Middle wheels	11·55 „
Trailing wheels	9·85 „
Total weight ...	32·05 „

The fire-box is 8 ft. long externally, with an inclined grate, on the South-Eastern Railway plan, for burning coal, which give a longitudinal section and sectional plan of the fire-box. The hind axle is thus brought under the fire-box about one-third of the length, and is enabled to take its proper share of the load; whilst the length of wheel base is moderated, and is bisected by the middle axle: advantages peculiar to this plan of fire-box. The fire-box measures 7 ft. 3 in. long inside, divided longitudinally by a midfeather, and has 27¼ square feet of grate. There are 189 tubes, 2 in. diameter, with ·62 in. clearance, within a 4 ft. 2 in. barrel. These are good proportions, according to current practice; but had there been only 160 tubes with ·75 in. clearance, in such a large barrel, it would, in the writer's opinion, have been decidedly better. The boiler is fitted with Giffard's injector. The housing for the engineman, with windows in the front and sides, is very good and complete.

The frame is composed of four longitudinal plates, carried from end to end, with suitable cross-plates to bind them. The outer plates are each of one slab, combining great strength and lightness; the usual construction of outer frame with double plates and timber packing has thus been superseded in this engine. The driving axle has four bearings, two inside and two outside, and the extreme axles have only outside bearings; and the old antagonistic action is set up, arising out of the unequal wear of the inside and outside bearings; the inside bearings next the cranks, receiving the full strain of the steam, will wear faster than the outside bearings, leaving the cranks unsupported, and shortening the duration of the axle; overstraining in that way also the connections of the inner and outer frame-plates, and thereby loosening them. On the other hand, this arrangement admits of large outside bearings and capacious axle-boxes for all the axles; an advantage which, unfortunately, the narrow gauge does not permit for inside crank-axle bearings. The drawing tackle of this engine is connected exclusively to the frame, and kept quite independent of the fire-box.

The valve gear is very substantially and firmly arranged: the expansion link is shifted, and the slide block is not overhung, but hung between the ends of the link which carries it. This engine is stated to be capable, with a working pressure of 120 lbs. per square inch, of taking a load of 480 tons on a level at 20 miles an hour, or a load of 250 tons up a gradient of 1 in 100 at 15 miles an hour.

A six-wheel-coupled goods engine, of excellent workmanship for the Midland Railway, was exhibited and manufactured by Messrs. W. Fairbairn and Sons. It has the ordinary rectangular fire-box with 14½ square feet of grate, and is fitted on the Midland plan, already referred to, for burning coal. The cylinders are 16 in. diameter with 24 in. stroke. The engine weighs in working order 32¼ tons, and is a thoroughly good engine of its kind; it is a type of the powerful goods engine usually met with on the old main lines of railway, and may be usefully compared with the Chatham and Dover goods engine last described, which is an engine of the same weight and power, but of a different and more recent class. In the first place, the weight is not so well distributed on the wheels of the Midland engine, being considerably in excess on the leading wheels, the loads being as follows:—

	Midland engine.		Chatham and Dover engine.
Leading wheels...	12·30 tons	... ...	10·65 tons.
Middle wheels ...	11·25 „	... ...	11·55 „
Trailing wheels...	8·70 „	... ...	9·85 „
Total weight...	32·25 „	... ...	32·05 „

showing in the former engine 3½ tons more load on the leading wheels than on the trailing, and in the latter only ¾ ton more; while the wheel base of the former engine is 16 ft. 6 in., or 1 ft. more than that of the latter, as the vertical fire-box of the former keeps back the hind axle. The frame of the Midland engine, like that of the other, has four longitudinal plates, with four bearings to the driving axle and outside bearings to the other axles; but the inside frame plates stop short at the fire-box, and are fastened to it by sliding joints, allowing for expansion of the boiler. The draw-plates are rivetted to and across the back of the fire-box, from which the whole of the drag is taken; and therefore, as the tractive force must be transmitted from the outside frame plates to the fire-box, they are very strongly united to it by brackets for that purpose. Thus the whole area of the frame behind the fire-box remains unemployed except as standing ground. This is, in the writer's opinion, an objectionable feature in the engine, without any countervailing advantage. Not only is the steam power transmitted circuitously, tending to over-strain and buckle the framing; but it arbitrarily subjects the boiler, already highly strained, to a great and unnecessary additional strain, which is now beneficially avoided in the other arrangements of the framing as already described.

The boiler tubes are well designed, being 2 in. diameter, 180 in number, and placed with ·62 in. clearance, in vertical rows; which accounts for the high character of these engines for keeping up the steam. The boiler is put together without angle iron, the plates being flanged at the end; the steam dome also is flanged and formed in one piece. For this purpose thick-edged plates are used, rolled to ⅝ in. or ¾ in. thick at the edge, to allow material to work upon in flanging. The advantages claimed for the thick-edged plates in their application are that they save a joint, including a row of rivets, and are stronger than angle-iron joints; and that the joints are cheaper and easier to make, and are not subject to grooving by corrosion. The dome joints being faced in the lathe, bad joints are prevented.

Of the mixed engines a six-wheeled four-coupled engine for the East Indian Railway, of 5 ft. 6 in. gauge, was exhibited and manufactured by Sir W. G. Armstrong and Co., with outside cylinders and the hind wheels coupled. The wide Indian gauge of rails, 5 ft. 6 in., admits of a large fire-box 4 ft. 1½ in. square inside, with a grate of 17 square feet, which appears too large for the cylinders of 16in.

diameter and 22in. stroke, and the wheels of 5ft. 7in. diameter. The boiler tubes, 157 in number, are 10ft. 11 in. long, 2¼ in. outside diameter, and they clear one another by ·56 in. These proportions would, in the writer's opinion, be improved by reducing the tubes to 2 in. diameter with increased clearance; and the reduction of heating surface would be amply compensated by the increased facility for circulation of the water and steam between the tubes.

The total weight of the engine in working order is 32¾ tons, which is too great for such an engine; 21¼ tons are available for adhesion, but very unequally divided between the wheels, the respective weights being—

Leading wheels	11·47	tons
Middle wheels	12·55	„
Trailing wheels	8·67	„
Total weight...	32·69	„

The leading wheels are 3 ft. 7 in. diameter, and the six wheels of the tender are 3 ft. 9 in. diameter, only 2 in. difference in size.

The slide valves have only ⅞ in. lap, but this is inadequate for a 16 in. outside cylinder, in which there is always more or less condensation of steam. The back pressure on the piston at high speeds must be considerable, as an insufficient lap prevents a full and free opening to the exhaust, which is required to be greater for moist than for dry steam. The foot-plate is furnished with an awning frame, to protect the engineman completely from the sun and to ensure ample ventilation: an object of vital importance in India. It is a very complete screen, the use of a weatherboard being unfavourable for ventilation.

A mixed engine was exhibited by the Great Eastern Railway, manufactured by Messrs. Robert Stephenson and Co., with six wheels, four coupled, and outside cylinders. The framing has but one longitudinal plate on each side from end to end, with inside bearings for all the wheels. With 17 in. cylinders and 6 ft. 1 in. driving wheels, which are more powerful than in the East Indian engine, the boiler is lighter, having only 13¼ square feet of grate instead of 17 square feet, with a shallower fire-box and a smaller barrel. Hence the total weight of the engine is less, and the weight is more equally distributed on the wheels, the loads being

Leading wheels	11·10	tons.
Middle wheels	10·70	„
Trailing wheels	10·05	„
Total weight ...	31·85	„

The leading wheels of 3 ft. 7 in. diameter are also very properly made uniform with the six tender wheels. The engine is reported to have run 45,000 miles without repairs; for which satisfactory result it is indebted to excellent design and workmanship, and no doubt also to the favourable distribution of the weight, and to the material of the tyres, Krupp's steel, which were apparently very little worn. A pair of tyres which had run 68,000 miles showed a wear of only about ¼ in. on the tread. Several of the driving and trailing wheel tyres of engines of the same class have run 60,000 to 70,000 miles without re-turning. The duration of these steel tyres is estimated at 100,000 miles on the leading wheels, and 150,000 miles on the middle and trailing wheels; but none have yet been worn out.

The barrel of the boiler is 3 ft. 10 in. diameter, and has 192 tubes, 1⅞ in. diameter, with ·62 in. clearance; which are fair proportions. The fire-box is fitted for burning coal, with a door deflector and jets of steam from the sides of the fire-box. The slide valves have 1¼ in. lap, with 5½ in. travel in full gear: very suitable proportions for outside cylinders, as before observed, for quick running and free exhaust.

Engines of this class are stated to work passenger trains averaging 16½ carriages, maximum load 35 carriages, at an average speed of 25 miles an hour, consuming 25 lbs. of coal per train mile; and goods trains consisting of 35 waggons, gross weight 300 tons, at an average speed of 20 miles an hour, consuming 30 lbs. of coal per train mile.

Of the tank locomotives the largest is that exhibited and manufactured by Messrs. G. England and Co., weighing 17 tons in working trim. It was designed for branch lines, and has six wheels with a 10 ft. wheel base, four coupled wheels of 4 ft. diameter, and cylinders 11 in. diameter. It is neatly arranged, with two tanks to hold 520 gallons very conveniently placed on the foot-plate, one on each side, enclosed out of view by a fence carried nearly from end to end of the engine. Of the weight, which is equally divided on the axles, two-thirds is available for adhesion. There are 158 boiler tubes, 1¼ in. diameter, with ·50 in. clearance, the boiler barrel being 3 ft. 8 in. diameter.

A neat, compact, and serviceable little tank engine was exhibited and manufactured by Messrs. Manning, Wardle, and Co., specially adapted and extensively used for collieries, ironworks, and public works. This engine was employed at he Exhibition under the author's superintendence in conveying the machinery on trucks from the unloading cranes to its destination in the western annexe along lines of rails laid down for the purpose; a duty in which it was of essential service. It has 9 in. outside cylinders, and four wheels coupled of 2 ft. 9 in. diameter, on a wheel base of 4 ft. 9 in. The area of fire-grate is nearly 5 square feet; and the boiler has 55 tubes, 2 in. diameter, with ·69 in. clearance, which is amply sufficient for circulation. The weight in working trim is 10¼ tons, equally distributed over the two pairs of wheels. The water tank is placed upon the barrel of the boiler, and holds 252 gallons. The coke boxes hold 7¼ cwts. Giffard's injector is employed. With a working pressure of 120 lbs. per square inch in the boiler, the exhibitors assume an effective mean pressure of 60 lbs. in the cylinders, which appears too low, but errs on the safe side; upon this they estimate the extreme tractive power as equal to moving 206 tons, but the actual power of the engine is no doubt greater.

The last and the smallest locomotive exhibited in the English Section is a tank engine for ironworks and collieries in South Wales, manufactured by the Neath Abbey Iron Co., for a gauge of 2 ft. 8 in., with 8 in. cylinders and four coupled cast-iron wheels of 2 ft. 4 in. diameter, 4 ft. apart centre to centre. The centre of the boiler is only 2 ft. above the rails. The boiler has 3¼ square feet of grate, and 59 tubes, 1¼ in. diameter and 6 ft. long, giving a total heating surface of 181 square feet; the gross weight in working order is 6·85 tons. The tank is on the back of the boiler. The engine is carried on volute springs. The engines employed in the Neath Abbey Works have a run of nearly one mile, with gradients varying chiefly from 1 in 15 to 1 in 26, with a small portion 1 in 100; they take the return empty waggons up the incline to the coal pits, the full ones going down by themselves. With 80 lbs. pressure of steam the regular duty of the engine is to take up 16 empty waggons or trams, weighing altogether 6·45 tons, or nearly the weight of the engine itself, in 7 minutes, or at the rate of 8 miles an hour. With 66 lbs. steam it can take up at the same speed 12 waggons weighing 4·50 tons.

(To be continued.)

IMPROVEMENT IN THE MANUFACTURE OF WIRE-ROPE.

It is well known to our nautical readers that there are two descriptions of wire-rope in use for ships' rigging, the best being called charcoal, and the second B B, the relative sizes and strength being usually compared as 3 in. charcoal, 7¼lb. per fathom, to 3¼ in. B B, 10lb. per fathom. The *Liverpool Daily Post* states that an important improvement has been made in the manufacture of the latter quality of rope, bringing it to the standard of charcoal rope, and at considerably less price. Six samples of this new manufacture, cut from a large parcel of rope shipped for a foreign Government, were recently tested at the Public Testing Works, Birkenhead, with the following result, as certified by Mr. Macdonald, superintendent. Breaking strain of six samples of the new manufacture of wire, "merchant navy brand," Garnock, Bibby, and Co., manufacturers:—

	Tons	cwt.
6 in. merchant navy with hempen cores ...	39	4
Card test for B B rope	36	0
3 in. merchant navy with hempen cores ...	12	17
Card test for B B rope	8	11
2 15-16 in. merchant navy with hempen cores	11	0
Card test for B B rope	8	8
2¼ in. merchant navy with hempen cores ...	6	14
Card test for B B rope	5	6
1¾ in. merchant navy with hempen cores ...	3	12
Card test for B B rope	3	5
1½ in. merchant navy with hempen cores ...	3	4
Card test for B B rope	2	5

The above result is considerably above the Admiralty test for charcoal rope: for instance, the Admiralty test for 3 in. charcoal rope is 11 tons 14 cwt.; 2¼ cwt. charcoal is 6 tons 7 cwt. In conclusion, considering that the merchant navy rope is considerably cheaper than charcoal, we have no doubt it will come into general use for rigging purposes.

TO CORRESPONDENTS.

Notice.—The NEXT NUMBER of the MECHANICS' MAGAZINE will be PUBLISHED ON THURSDAY, the 24th inst., at Two o'Clock; and Advertisements for that Number must be received at the Office Before Six o'Clock on Wednesday evening.

The Mechanics' Magazine is sent post-free to subscribers of £1 1s. 8d. yearly, or 10s. 10d. half-yearly, payable in advance. Post-office orders made payable to Mr R. A. Brooman, of 166, Fleet-street, E.C.

Advertisements are inserted in the Mechanics' Magazine at the rate of 6d. per line, or 5½d. per line for 6 insertions, 5d. per line for 13 insertions, 4½d. for 26 insertions, and 4d. a line for 52 insertions. Each line consists of about 10 words. Woodcuts are charged at the same rate as type. Special arrangements made for large advertisements.

All communications should be addressed to the Editor, 166, Fleet-street.

To insure insertion in the following number, advertisements should reach the office not later than 5 o'clock on Thursday evening.

D. B. F.—The diameter of the] supply pipe for a single cylinder water-pressure engine, may be found by multiplying the diameter of the cylinder by ·41.

Iron (Dunfermline).—The first part of your letter is so confused that we are at a loss to understand its meaning. The yield of a puddling funace averages about 18 tons per week.

C. F. (Liverpool).—Place your crank handle 3 ft. from the platform, and make it 15 in. to 17 in. radius.

S. B.—No. 357, 1862.

Correspondence.

NARROW GAUGE ENGINES.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE".

Sir,—Having read the various remarks published in your Magazine upon the above subject, we feel in some measure called upon to offer a few words in explanation; more particularly so, after reading the letter of Messrs. Manning and Wardle, published in your journal of last week, wherein it might be inferred by any one reading it, that we had made the engines for the Festiniog Railway Company from a design supplied by them, although we are fully satisfied by a letter received direct from themselves, that *they* are *now* quite convinced that we did not even see their plans.

The statement they make in their published letter, with reference to the plans, we believe to be strictly correct, and were quite sufficient to induce them to believe, "as they state in their letter to us," that Mr. Holland had copied the drawings sent to Mr. Spooner, and handed them to us for execution; but, to do Mr. H. justice, he was not guilty of anything of the sort. That gentleman brought to us, in the month of September, 1862, an original sketch of a locomotive engine, asking us if we were disposed to make some such engine for the Festiniog Railway Company, capable of taking a load of 25 tons up an incline of 1 in 70, at the rate of 6 miles per hour, upon a gauge of 2 ft. only. In this we saw no difficulty, and at once said, we could do so; but, that if we made the engines at all, it would be from our own drawings, to which he at once assented, as he did not seem to attach any degree of importance to the sketch he brought with him, as he wished to leave the design and execution of the engines entirely in our hands, so that the company might hold us responsible for the same. All they desired was, to get an engine, capable of performing the amount of work required, upon their line of 2 ft. gauge; and he took his drawing away again, which we have never seen since, but is probably the same drawing submitted to Messrs. Manning and Wardle, on the 28th of October following, as stated in their letter.

After some correspondence between ourselves and Mr. Spooner, the company's engineer, we sent him an outline of the engine we purposed making, without any details, engaging that the engine when made should do the work required; and it is very satisfactory to all parties, that the engines now at work are capable of taking up the incline double the load, and at double the speed that was contracted for.

We may state that we never saw any difficulty, o any considerable degree of merit, in designing these engines, when first applied to; but, when we heard the various opinions of several engineers of eminence, quoted in Parliament, as to the impracticability, we began to inquire of ourselves whether we were really correct in our calculations, and made a thorough revision of the subject, when we became more than ever convinced of its practicability. The fact is, they are simply a reduction of the light locomotive engine we exhibited in the Great Exhibition of 1862, which engine was barred from receiving a

prize medal, "as Colonel Yolland, the foreman of the Jury of Class 5, in which locomotives were exhibited, told our Mr. England," that, on account of our having received the prize medal of the Exhibition of 1851 for a similar engine, the jury could not award us another medal for the engine, which was practically the same—thus showing that we have been in the habit of making this sort of engines for many years, which were well known as "The Little England" class of engine, we having made them several years previously to 1851.

In order to be perfectly safe with reference to the centre of gravity upon so narrow a gauge, we pitched that, in our design for the Festiniog engines, precisely the same as the centre of gravity was found in a number of engines we had then just completed for the Great Western Railway Company, which are daily running at the rate of fifty miles per hour; we therefore felt that the small engines would be equally safe upon their narrow gauge, as the result has proved; hence, it will be seen that the subject was nothing new to us, as we considered it only as a matter of ordinary business; and if any such eminently practical engineers as the late Mr. Robert Stephenson stated, that to make such engines for the 2 ft. gauge was impracticable, we feel it must have been under some misconception of the case submitted to them.

We may also state what we know of the circumstance that gave rise to the report, which appeared in many of the papers, giving Mr. Holland the credit of the design of the Festiniog engines. The facts are, that the day of opening the Festiniog line with locomotive engines was made a grand gala day, and a large party went up the line, from Port Madoc into the mountains of the Festiniog Slate Quarries, "the source of their traffic," a distance of 14 miles, with flags flying, bands playing, and other demonstrations of rejoicing; on which occasion, two engines were employed—the first driven by our Mr. England, and the other by one of our staff who had been sent down to put the engines to work on the line—the first engine having a train of 20 waggons, and the second engine 24 waggons, all fitted up with seats and crowded with people; they thus travelled as two separate trains at a distance of about 500 yards apart at a speed of 12 miles an hour.

Having enjoyed very much the trip up the mountains, the whole party, consisting of many of the quarry proprietors and the principal gentlemen of the neighbourhood, amongst whom were Mr. C. M. Holland and many of his friends, "who are extensive quarry proprietors," returned to Port Madoc, and sat down to a sumptuous dinner, in the Townhall, where, in an after-dinner speech, proposing the health of Mr. C. M. Holland, the remarks were made, attributing to him the design of the engines they had seen that day working so efficiently; but to do Mr. H. justice, he immediately spoke to Mr. England, repudiating such remarks, who said, "Never mind, let it pass; you are known here; and it will do you no harm." Hence, nothing was said publicly in contradiction, and the whole affair being extensively reported to the local journals, gave circulation to these erroneous reports, and very naturally called forth the letter from Messrs. Manning and Wardle.* Trusting that these few remarks will explain the subject clearly to yourself and the public,

We remain, Sir, yours very faithfully,
G. ENGLAND AND CO.

Hatcham Iron Works, London,
December 16th, 1863.

Miscellanea.

A smart shock of an earthquake was experienced on the night of Wednesday week, at Nimes, Avignon, Montpellier, and other towns in the South of France.

The new contract between the Government and the Montreal Ocean Steamship Company has just been signed by the Postmaster-General, subject to the approval of Parliament. The contract is for five years. The amount payable by Government is £54,500 currency (218,000 dols.) per annum. The contract provides that the vessels shall slacken speed or stop whenever danger is feared from fog or icebergs; and time thus lost is not to be regarded as a default on the part of the contractors. It has also been very properly made a condition of the contract that the steamers shall not approach Cape Race in bad weather.—*Toronto Globe.*

* It is only just to Mr. Holland to state that he never, "to our knowledge," in any way attempted to appropriate the remarks in his favour, but always said that it was perfectly ridiculous, as he had nothing whatever to do with the matter.

Belgium possesses an order of merit for industrial and agricultural labourers. The decoration worn by the members has just been modified by royal decree, and now consists of a medal bearing an emblematical figure representing manufactures or agriculture, as the case may be, upon a black enamel ground, surrounded with a red border. The design is enclosed within a fillet, on which are inscribed the words "Skill; morality." Around the whole is a wreath of laurel in blue enamel for artisans, and green for agriculturists, surmounted by the arms of the country, suspended to a royal crown. The decoration is suspended to a ribbon of the national colours, which, however, cannot be worn without a medal.

There were a further series of experiments on Friday in connection with floating targets. At a thousand yards the 600-pounder Armstrong sent a steel shell through the "Warrior" target (which had been moored out at sea for the purpose of being fired at); but the 300-pounder unfortunately missed it four times—the third shell bursting in the gun—and hence there was no opportunity afforded of comparing the relative effect of these pieces. It may, however, be added that the effect of the shell's bursting was terrific, and shook the target nearly to pieces. The initial velocity of the 600-pounder projectiles was 1,150 ft. per second.

The Emperor of Russia has commanded a large supply of heavy steel shot and shell to be forthwith forwarded to the Imperial arsenals. The manufacture of these missiles is partly to be carried on in Russia and partly in England, Messrs. John Brown and Co., of the Atlas Works, Sheffield, have already received directions to prepare with all despatch for shipment 5,000 large shot, carefully prepared under the Bessemer process.

The estimates of the probable supplies of cotton for the year 1864 have been published, and the several opinions, with the names of the several authorities, merit insertion together:—

Mr. Cheetham	2,445,000 bales.
Messrs. Neill	2,665,000 „
Mr. Ashworth	2,825,000 „
Mr. Whitworth	2,915,000 „

The total imports of the year now drawing to a close will have amounted, as has been conjectured from the returns already published by the Board of Trade, to about 1,910,000 bales. Thus the least sanguine among those qualified apparently to forecast the future counts that next year we shall receive one quarter as much again as we have received this year, while the most sanguine among them puts the augmentation at half as much again.

On the 1st prox. an Act passed in the late Session for the more effectual condensation of muriatic acid gas in alkali works will take effect. The term "alkali" is to mean every work for the manufacture of alkali, sulphate of soda, or sulphate of potash in which muriatic gas is evolved. The object of the statute is to secure the condensation of the gas to the satisfaction of the inspector or sub-inspector appointed under the Act. If it should appear to the Court before whom any proceeding for the recovery of a penalty is instituted that 95 per cent. at least of the muriatic acid gas evolved has not been condensed, a penalty not exceeding £50 will be levied, and for a second offence £100. The owner is to be liable for the offence in the first instance, unless he prove that the offence was committed by some agent, and without his knowledge, in which case the agent, &c., is to be liable. The Board of Trade is to appoint inspectors, and alkali works are to be registered.

A short time ago the divers engaged searching the pool where the "Royal Charter" broke up four years ago came upon a very rich store of gold. They found in the same spot, in the course of a few days, about £1,200 in sovereigns and a bar of pure gold, weighing 9½ lb., which was brought up to London this week. The treasure was far from being exhausted, when the storm came on and put a stop to the diving operations for the season. Messrs. Gibbs, Bright, and Co., the owners of the vessel, sold about a year ago, to some persons in Anglesea, all claim to the treasure found on the spot, and it is said that the speculation has already paid 300 or 400 per cent. profit, although the cost of working it is very considerable.

A pyramid has recently been discovered in California resembling the pyramids of Egypt in every detail of its construction, but very much smaller. The stones of which it is composed are about 6 ft. long, and vary in thickness from 1 ft. to 3 ft.

A lecture on "The Science and Practice of Electro-Metallurgy" was delivered on Wednesday last, by Mr. A. B. Midlane, at the Whittington Club. The subject was well illustrated by fine examples of the art, lent by Messrs. Elkington and Co., R. W. Kennard and Co., and the General Foundry Company. The examples of the last-named firm were of subjects of particular interest to the building trades, being bassi-relievi designed for the ornamentation of stove grates and chimney-pieces. The next lecture is announced for the 13th proximo, on "The Metal Work of the late Exhibition," and is to be delivered by the Rev. Charles Boutell, M.A.

Patents for Inventions.

ABRIDGED SPECIFICATIONS OF PATENTS.

THE Abridged Specifications of Patents given below are classified, according to the subjects to which the respective inventions refer, in the following Table. By the system of classification adopted, the numerical and chronological order of the specifications is preserved, and combined with all the advantages of a division into classes. It should be understood that these abridgements are prepared exclusively for this Magazine from official copies supplied by the Government, and are therefore the property of the Proprietors of this Magazine. Other Papers are hereby warned not to produce them without an acknowledgement:—

BOILERS AND FURNACES—*none.*
BUILDINGS AND BUILDING MATERIALS, 1177, 1189, 1207, 1214, 1219.
CHEMISTRY AND PHOTOGRAPHY, 1156.
CULTIVATION OF THE SOIL, including agricultural implements and machines, 1176, 1185, 1188, 1190.
ELECTRICAL APPARATUS, 1199, 1200,
FIBROUS FABRICS, including machinery for treating fibres, pulp, paper, &c., 1158, 1166, 1167, 1179, 1192, 1194, 1197, 1208, 1210.
FOOD AND BEVERAGES, including apparatus for preparing food for men and animals, 1201, 1205, 1209.
FURNITURE AND APPAREL, including household utensils, time-keepers, jewellery, musical instruments, &c., 1165, 1168, 1169, 1170, 1182, 1184, 1195, 1196, 1198, 1204, 1211, 1212.
GENERAL MACHINERY, 1161, 1162, 1163, 1164, 1178, 1193, 1206, 1216, 1218.
LIGHTING, HEATING, AND VENTILATING, 1213, 1215.
METALS, including apparatus for their manufacture, 1181.
MISCELLANEOUS, 1157, 1173, 1202, 1217.
ROADS AND VEHICLES, including railway plant and carriages, saddlery and harness, &c., 1172, 1180, 1183, 1191:
SHIPS AND BOATS, including their fittings 1171, 1186, 1203.
STEAM ENGINES, &c., 1159, 1160, 1174, 1175, 1220.
WARFARE, 1187.

1156. W. CLARK. *Improvements in coating wrought or other iron to protect it from corrosion or oxidation.* (A communication.) Dated May 8, 1863.

The patentee claims—1, obtaining upon the surface of iron a coating composed in part of metallic aluminium, by covering it with a compound of porcelain frit, white lead, felspar and fat, alum or potash clay, and subjecting it to a single baking operation, as described. 2, obtaining upon the surface of iron a coating of metallic aluminum, either by covering it with a paste of fat, alum or potash clay, and boracic acid, and subjecting it to a baking operation, or by fusing the said paste and dipping the iron, heated to a red heat, in the molten fluid, and after it is cold applying the coal or kerosene oil, as described. *Patent completed.*

1157. E. O. BORT. *Improvements in tanning hides and skins.* (A communication.) Dated May 8, 1863.

By the use of this invention any hides or skins can be tanned, although they have not been previously deprived of their hair or wool, which will be preserved; they are also rendered tough, supple, and waterproof. Skins thus prepared are fit for coverings for the feet, carpetings, knapsacks, and other similar objects. The skins are thoroughly penetrated by the tannin, and in a shorter time than by the usual process. The substances which the patentee makes use of are the following:—Tan or oak bark, cashoo or catechu, sumach—a plant known in commerce as "divi divi" fennel, and common salt. *Patent completed.*

1158. C. F. BIELEFELD. *Improvements in the manufacture of sheets, slabs, and other articles where fibrous materials are employed.* Dated May 8, 1863.

In carrying out this invention, the patentee takes woven or other suitable fabric, such as fabrics of woven cocoa-nut and other fibres, felt paper, dry hair-felt, and such like, and he thoroughly saturates the same with a compound of water glass (soluble silica), clay, and lime, with or without metallic oxides: the proportions he prefers are as follows:—Clay, 1 lb.; lime, 1 lb.; pumice stone, 1 lb.; pulp, 6 lbs.; water-glass, 8 lbs. He also makes a plastic material composed of the same, adding a quantity of paper pulp, or other like material, in about the following proportions:—2 lbs. of a mixture composed of equal parts of clay, lime, and pumice stone; 8 lbs. of water glass; and 2 lbs. of pulp, which is trowelled over the prepared pieces of fabric, filling up all the interstices of the fabric. Where greater thickness is required, he places two or more thicknesses together, and gauges or trowels the surfaces to the thickness or purpose required. He also makes thick boards by the like mixtures with paper pulp in a very fluid state. The mixture must be kept in motion in order that it may become thoroughly incorporated. It is then poured into frames according to the thickness required. To the bottom of the frame he fixes either gauze wire or perforated metal. *Patent completed.*

1159. G. T. BOUSFIELD. *Improvements in steam engines.* (A communication.) Dated May 8, 1863.

The patentee claims—1, inc[illegible] average diff. between the temperature [illegible] cond. cooler and the temperat[illegible] water

combination of a cooler, or of a surface condenser, with a double eduction, in the manner described; 2, condensing the steam discharged from the cylinder of a steam engine by the first eduction, by delivering the steam into the hot well of the engine, as described; 3, taking the steam from the cylinder by the first eduction on the induction side of the piston through openings made midway in the length of the cylinder, without the intervention of a valve moved by the mechanism of the engine, as described; 4, delivering the steam discharged by the first eduction from the cylinder of a locomotive engine into the feed-pipe between the tank and the force pump, as described. *Patent completed.*

1160. W. THOMPSON. *Improvements in obtaining motive power, which improvements are applicable in part for raising or forcing fluids into steam boilers, tanks, and other vessels.* Dated May 9, 1863.

This invention has for its object improvements—1, in obtaining motive power; 2, in raising fluids; and 3, in raising and forcing fluids into boiler tanks and other vessels. The invention consists of an apparatus, the principal parts of which are a rotary double wheel or wheels, which turn together, one being impelled by the other, formed as hereinafter described, and fitted and caused to rotate in suitably formed enclosed cases, through which steam or other elastic vapour or fluid passes. The first of these wheels the patentee denominates the motive wheel or motor, and the second the impelling wheel or impeller. The motor is operated upon by the force or momentum of the steam, vapour, or fluid, and the impeller operates upon the fluid to be raised or forced. When the apparatus is used for driving machinery, a drum, pulley, or crank takes the place of the second wheel or impeller, and a simple supply and discharge pipe only is required to be fitted to the motor case. When the apparatus is required to raise liquids—as, for instance, water from a well or mine of considerable depth—the discharge pipe is fitted with a number of branches opening into the rising main; and, when required to raise and force liquids into a boiler or other vessel against pressure, the discharging pipes are joined into one, and fitted with the valves and sliding cone or cones described. *Patent completed.*

1161. J. STRICKLAND. *Improvements in laying veneers on to surfaces, in applying the glue for that purpose, and in apparatus employed.* Dated May 9, 1863.

The patentee claims—1, laying veneers on to surfaces by so applying the requisite pressure by means of rollers or their equivalents that it is exerted upon only a small portion of the surfaces to be united at one time, the whole of the surfaces being subjected in a progressive manner to such pressure; 2, constructing apparatus for laying veneers on to surfaces in which the veneers and surfaces are caused to pass between rollers or their equivalents that are made to exert the requisite pressure upon them as they pass through, substantially as described; 3, applying the glue to surfaces to which veneers are to be applied by means of revolving brushes, as set forth. *Patent completed.*

1162. S. WILSON. *Improvements in hoops or bands for fastening bales, and in machinery or apparatus for making the same.* Dated May 9, 1863.

In performing this invention, the inventor makes the ends of the bands with V or other shaped recesses and projections which fit into each other. The ends of the bands when brought together are securely held by a clip, which is slipped over them. The clips are made of malleable cast iron, or of sheet iron or wire bent over a mandril. In unfastening a bale secured by the above-described improved hoops or bands, it is only necessary to slide the clip beyond the recesses and projections, when the bands are set at liberty, and may be used over again. *Patent abandoned.*

1164. J. NORIE. *Improvements in making moulds for casting, and in apparatus therefor.* Dated May 9, 1863.

This invention is not described apart from the drawings. *Patent completed.*

1165. J. PAGE and A. T. WAYNE. *An improvement or improvements in the manufacture of pens.* Dated May 9, 1863.

This invention consists in making pens from aluminium alloyed with copper, or what is generally termed aluminium bronze. *Patent abandoned.*

1166. J. BRIERLEY. *Improvements in dyeing knickerbocker yarns and textile fabrics manufactured of or from such yarns.* Dated May 9, 1863.

This invention consists in having the fibres, or such of them as are intended to be dyed bright colours, mixed, spun, and scoured, or washed before drying them. The dyeing is then effected either upon the yarns before weaving, or upon the fabrics made of such yarns by any of the known methods of dyeing mixed fibrous substances. *Patent abandoned.*

1167. W. BOALER. *An improved dryer fabric for paper making.* Dated May 9, 1863.

This invention consists in the use of a peculiar cloth, which is composed of many webs and threads all bound together in the weaving, and forming one cloth, either twilled, plain, or chain. By preference, he employs cotton, but linen, wool, or any textile or fibrous material could be used either wholly or in combination with cotton. *Patent completed.*

1168. E. R. CLARK. *An improvement in the construction of portable wine cases or bins for domestic use or export and a picnic chest combined.* Dated May 9, 1863.

In carrying out this invention the patentee employs an ordinary deal or other wood box or case, and provides two partitions from top to bottom, fixed at about an inch from each end or side, as the case may be, each of such partitions having as many circular holes cut in them as may be required, and each of a little longer diameter than the usual size of wine bottles. The centres of the ends or sides of the said box or case are either grooved of a dovetail shape, or plain, square, or provided with slips to form a groove fixed at about half an inch apart to receive sundry pieces of wood, one of which is fixed at the bottom of the said box or case; the first tier of bottles being placed in the case, a piece of wood is inserted down the groove, and so on until the case is filled, when it is so arranged that one piece comes level with the top edge of the case, and consequently, when the lid is closed the bottles are securely fixed. *Patent completed.*

1169. N. LEGENDRE. *Improvements in the construction of scissors.* Dated May 9, 1863.

This invention consists in the construction of scissors in such manner as to cut two pieces or threads at one and the same time, the scissors being worked in the ordinary manner as hereafter described. Two arms or blades terminating at one end in rings are jointed together at the other end and about which point they are free to move. Two other arms shorter than the first are jointed at their rear end, and are united by screws or rivets to the first-mentioned blades, and which cut on their outside edges whilst the others cut on their inside edges. If now, for example, the scissors are opened, and the foremost or those points which are jointed together are introduced into a loop of tulle, and the instrument is pushed forward until the loop is stretched; on closing the scissors the two ends of the loop are cut at one and the same time, and by the same motion. Scissors made in this manner may be fitted to a cross bar, and arranged so as to suit certain designs, and thus engage one series of loops in the scissors which follow, all being worked by a single motion. *Patent abandoned.*

1170. R. A. BROOMAN. *Improvements in the manufacture of lampblack.* (A communication.) Dated May 9, 1863.

This invention consists in manufacturing lampblack by the pulverization of charcoal in manner hereafter stated. The inventor takes cylindrical vessels one or more, and mounts them upon trunnions, so that they may be rotated at any speed required; an aperture in the side serves for the admission of the charcoal to be pulverised, and also for the insertion of a number of balls or spheres of iron, glass, stone, marble, or other like suitable material. The aperture is then covered with wire gauze or perforated plate, which only affords passage to the charcoal when in a state of fine powder. The cylinders are caused to rotate, and the charcoal becomes reduced to impalpable powder or lampblack under the action of the balls. *Patent abandoned.*

1171. J. B. WOOD. *Improvements applicable to the defending of ships or vessels and forts when armour plating is employed.* Dated May 9, 1863.

The object of this invention is to apply in combination with, and as a backing to, armour plating, thick sheets, blocks, or masses of the hides of buffaloes or other animals, which are first disintegrated or ground into a plastic condition, and then formed into sheets, blocks, or masses suitable for being interposed as a backing between the armour plating, and the body of a ship, vessel, or fort. *Patent abandoned.*

1172. J. BURRELL. *Improvements in machinery for cutting the teeth of bevelled wheels.* Dated May 9, 1863.

For the purpose of cutting the teeth of bevel wheels, the patentee mounts the wheel to be cut on an axis, which is held stationary whilst the teeth are cut, except that in passing from one tooth to the next it is turned through a portion of a circle, corresponding with the number of teeth to be cut. In connection with the axis there is a division plate, by means of which the angular motion required to be given to the wheel in passing from tooth to tooth is accurately measured. The teeth of the wheel are cut by means of a planing or shaping tool held in a carrier or tool box, which is made to slide to and fro on a guide frame, as in a shaping machine; but the guide frame, in place of being made stationary, is made capable of being moved at one end in such manner as to allow it at the other end to move both up and down and sideways, so that the tool, as it travels to and fro on the guide frame, may give the required contour to the side of the tooth which is being cut. The point of the guide frame is also so arranged that the tool constantly moves radially to and from a fixed centre point, whatever be the position of the guide frame, and the bevelled wheel to be cut is so placed, that the apex of the cone of which it is a frustrum coincides with the said centre point, to and from which the cutter is caused to move. The apparatus is also so arranged that the cutter can, when required, cut up to the centre point about which the one end of the guide frame turns. With these ends in view, the following construction or combination is adopted:—The guide frame is formed with trunnions at its end, which are mounted in bearings on a semicircular slide, which is capable of sliding in a semicircular groove struck from the centre point, to and from which the cutter is constantly moved. The vertical motion of the guide frame is on its trunnions, and its lateral motion is by the semicircular slide moving in its guides or groove. The vertical motion, which is slow and uniform during the cut, is given by a train of wheels, the last of which gears with a toothed arc fixed to the guide frame, and the lateral motion of the guide frame is given by a pattern surface of a form suitable to produce the contour of tooth desired. The carriage of the axle on which the wheel to be cut is placed, is arranged to slide on a bar, and to be fixed thereon in any desired position. The bar on which the carriage slides is arranged to be raised and lowered and retained in any required position, and the axis on which the wheel to be cut is placed, is arranged to be set and adjusted on its carriage to the angle required for any particular bevel wheel. *Patent completed.*

1173. C. H. G. WILLIAMS. *Improvements in the manufacture of colouring matters.* Dated May 9, 1863.

In carrying out this invention, the patentee prepares a blue colour, suitable for dyeing and printing, and mixes one part by weight of rosaniline, or one of its salts—such as the acetate, hydrochlorate, or sulphate—with eight parts of oleate of aniline, or with four parts of oleic acid, and four parts of aniline. He then heats the mixture to a temperature between 300 deg. and 400 deg. Fahr., until the whole is converted into a deep blue mass, soluble in spirit of wine. Any oleic acid and aniline remaining in the mixture may be removed by first boiling with dilute sulphuric acid, and then with coal naphtha or photogen. The impurities are thus removed and the colouring matter remains behind in the form of a coppery or bronze-like mass. For the purpose of dyeing, it is merely necessary to dissolve this bronze-like matter in spirit of wine and add it to the bath. The word aniline, in this specification, is intended also to include toluidine and other substances very closely resembling aniline and which are known as the homologues thereof. *Patent completed.*

1174. J. BURRELL. *Improvements in salinometers.* Dated May 9, 1863.

For the steam boilers of sea-going steam ships, in order to determine from time to time the amount of salt contained in solution in the water in the boiler, the patentee leads two pipes, the one from the top and the other from the bottom of the boiler. These pipes he connects with a glass tube, so that the said tube forms a connection between the two pipes. The arrangement is thus very similar to the ordinary water gauge of a steam boiler, but differs from it in the employment of a considerable length of pipe above and below the glass tube. In the upper pipe into which the steam from the boiler enters condensation is constantly going on, and the water thus distilled runs down and fills the lower pipe. The water stands in the glass tube as in an ordinary gauge tube, but its level will not be the same as that in the boiler, for the weight of the salt water in the boiler will raise the column of distilled water in and above the glass tube to a height considerably above its own level. An ordinary gauge tube gives the water level of the boiler; and this, when compared with that of the salinometer gauge tube, will indicate on a scale attached, or by reference to a table the density of the water in the boiler. *Patent completed.*

1175. J. H. JOHNSON. *Improvements in rotary engines.* (A communication.) Dated May 9, 1863.

This invention relates to a peculiar construction and arrangement of rotary engine, and consists in the employment of two pistons, each filling about one quarter of the annular steam space surrounding the main shaft inside the cylinder. These pistons work loose upon the main shaft, but are each connected by a long collar or boss with a disc outside the cylinder, on the periphery of which are formed two ratchet teeth or notches on diametrically opposite sides of the disc, which take into a fixed detent or stop, the object of this detent being to prevent the rotation of the disc, and its corresponding piston in other than one direction. The steam is admitted into the cylinder between the contiguous faces of the two pistons (which are always at the completion of each stroke nearly close together) by means of two distinct ports or passages made longitudinally in the shaft, each communicating with a transverse passage passing diametrically through the shaft from side to side. At the steam inlet extremity of the main shaft there is a disc which answers as an expansion valve, being provided with an opening which exposes only one of the two longitudinal passages at a time, but as the shaft rotates it follows that each passage is open alternately. In front of this disc there is a steam chest, into which the steam is conducted by a steam pipe from the boiler. Close to each of the notched discs hereinbefore referred to there is keyed on to the main shaft another notched disc, and into the latter engages a pawl, carried by each of the notched discs first referred to, which are connected direct to the loose pistons. The steam enters the cylinder between the faces of the two pistons, and tends to separate them in opposite directions; but as one of them is prevented from rotating in a backward direction, by the detent or stop above referred to, the other alone is free to rotate, and describes a half revolution. During its semi-revolution it carries round with it through the discs and connecting pawl the main shaft, whereupon the second steam passage is opened, and steam again enters, but by the second transverse port between the contiguous faces of the pistons, and forces round the piston which was previously held stationary, whilst that which has last operated is held in turn by its detent and prevented from rotating backward. The shaft is thus carried round continuously by a series of half-revolutions of the two pistons acting alternately upon it in one and the same direction. *Patent abandoned.*

1176. J. LEE and M. GUTTERIDGE. *Improvements in agricultural implements.* Dated May 9, 1863.

This invention relates to ploughs, harrows, haymaking machines, horse rakes, hand rakes, and subsoil looseners, and consists in constructing such implements as follows—1, as regards ploughs, this invention consists in forming the handles and beams thereof of wrought-iron gas-tubing or piping, such as is at present used by gas fitters, the object being to lessen the weight of ploughs without lessening the strength and durability thereof; 2, as regards harrows, this invention consists in forming the same of gas tubing, and in adapting to harrows an oscillating motion, derived either from two cranks, or from two eccentrics working on a shaft supported by two wheels in front, the joints being so constructed as to allow of the oscillation of all the harrows. As regards haymaking machines, this invention consists of a new and improved method for throwing out the socket pinions simultaneously from one side of the machine, and putting them into either forward or backward motion as required, without resorting to a hollow tube or main axle for fastening on and carrying the heads which contain the requisite gearing for working the time barrel, thus avoiding weakness and liability to break across at the angles of the long slot, hole, or groove, in which the reversing forks slide forward or backward. *Patent abandoned.*

1177. B. HARGREAVES. *Improvements in tiles for drainage or sanatory purposes.* Dated May 11, 1863.

This invention consists in making earthenware tiles, or tiles of other material, of a conical or taper shape, or otherwise of a conical or taper ended shape (whether plain or fluted on the surface, or depressed at the ends), so that the smaller end of one tile fits into the larger end of another or next adjoining tile, thus preventing the ends becoming disconnected from each other by the settlement of the ground on which they rest, such sides also not admitting dirt or other obstructions getting in at the junctions, and impeding the flow of water or other liquids through

them. The said tiles also admit of being laid in curved courses in the ground or having branches affixed to the sides of them on the conical or taper principle of joints as aforesaid for cross drains, the whole being thereby coupled together, and forming a permanent and endnring system of drainage. *Patent completed.*

1178. R. BURGESS. *Improvements in machinery or apparatus for marking, etching, engraving cylindrical and other surfaces.* Dated May 11, 1863.

This invention relates to those descriptions of marking, etching, or engraving machines in which the pentagraph is employed for giving the required movements to the roller or surface to be operated upon, and consists of certain improved arrangements for supporting the ordinary floating table which carries the roller or surface, in order that the table may be moved longitudinally and transversely with ease and certainty. The plate or surface of the table rests near each end upon two discs or wheels supported on a triangular shaft, placed transversely across the machine, and having bearings so that it can revolve. The two shafts are parallel with each other, and their surfaces form beds on which run pulleys or guide rollers carrying as many bars as there are surfaces, which bars are connected to a box or frame fixed to each disc or wheel. *Patent completed.*

1179. C. and W. SHORROCK. *Certain improvements in power looms for weaving.* Dated May 11, 1863.

This invention consists—1, in the novel and peculiar arrangement of apparatus for applying or regulating the power or friction of the brake on the warp beam, whereby the patentees are enabled to keep a constant pressure upon such beam during the operation of weaving; but should there be any imperfection in the weaving, necessitating a reverse motion of the said warp beam, such reversing is accomplished without any pressure upon the beam by the said brake. The improved arrangement of mechanism may be described as follows:—Upon one end of the warp beam is fixed a cylindrical bush supplied with a ratchet wheel, such wheel being acted on by a pawl or catch secured to a grooved ring or hoop encircling the before-mentioned bush, a strap of leather or other suitable material being fitted into the groove of the ring, the pressure being exerted upon it by means of a clip or brake; it is so arranged that when such clip is tightened, it shall exert a pressure upon the warp beam through the medium of the before-mentioned pawl and ratchet wheel during the operation of weaving; but should any reverse or backward motion be given to the warp beam, the pawl or catch slips over the teeth of the ratchet, thereby allowing the bush encircling the warp beam to revolve freely within the grooved ring without any pressure, the only pressure upon the warp beam being effected by the contact or resistance of the pawl or catch against the ratchet wheel. Upon the adjustable pressure clip is a small bowl acted upon by a spring in such a manner that it shall always cause an even tension to be given to the warp. A second part of these improvements consists in the employment and use of bowls or pulleys secured below the healds, and above the treadles to which the healds and treadles are attached, by means of straps; such straps, when the treadles are in motion, partially wrap or fold upon the before-mentioned pulleys, causing by their connection with the healds a constant rise and fall or shedding to such healds. These bowls or pulleys act as intermediate carriers between the treadles and the healds, lessening the strain or weight upon the healds, thereby causing such healds to be more durable and lasting, also easier in their action upon the warps. *Patent completed.*

1180. C. L. V. TEXAC. *A new wrought-iron railway sleeper.* (A communication.) Dated May 11, 1863.

This invention is not descrbed apart from the drawings. *Patent completed.*

1181. C. L. V. TEXAC. *Armour plates of hammered or rolled wrought iron, the whole of the rivets being protected against the direct blows from the cannon shots.* Dated May 11, 1863.

This invention is not described apart from the drawings. *Patent abandoned.*

1182. J. PARKINSON. *A new or improved mode of manufacturing tablets to be used for monumental purposes.* Dated May 11, 1863.

This invention consists in forming tablets to be used for monumental and other purposes of earthenware, the inscriptions thereon being raised or sunk by means of moulds. *Patent abandoned.*

1183. R. A. BROOMAN. *Improvements in coupling and disconnecting carriages on railways, and in machine employed therein.* Dated May 11, 1863.

This invention is not described apart from the drawings. *Patent completed.*

1184. J. S. GUIBETTE. *An improved inhaling apparatus.* Dated May 11, 1863.

This apparatus consists of a vessel fitted as hereinafter explained, through which air is to be drawn before being inhaled. This vessel is provided with an inlet tube for the admission of air, and the mouth of this tube is covered by one, two, or more loose cones or thimbles which fit over one another, and in the crown of each of which is an aperature. The aperture in the lowest cone is the largest and in that next above it is smaller, and so on, the aperture being smallest in the top cone. By these apertures the admission of air is graduated according to the requirement of the particular case being treated. There is also an outlet pipe from the vessel, which opens into a tube terminating in a mouthpiece, and of sufficient length to cause the condensation of any condensible vapours before reaching the mouth of the patient. The inventor prefers the employment of loose perforated cones for regulating the admission of the air, but other means of regulating may be adopted. *Patent abandoned.*

1185. J. SHANKS. *Improvements in machinery for cutting or shearing the edges of grass or turf.* Dated May 11, 1863.

Under one modification, this implement consists of a cast iron frame with handles, somewhat similar to the form of a lawn mower. It is fitted with a roller, which is keyed to a shaft that works in two bearings, one at each side of the frame. The front part of the frame has fitted to it two brackets containing bearings for a shaft, on which is placed one or more small rollers which are used for steadying the implement in working. These brackets may either be fixed or made to slide up or down by means of a slot, and fastened to the side of the frame with a bolt and nut to each. On the back roller shaft is keyed a toothed wheel, which gears into a pinion placed on a counter-shaft, and may be either keyed on the shaft or loose, and provided with a clutch to slide on a sunk key on the shaft for the purpose of putting the implement out of or in gear as may be required. On one end of the counter-shaft is fastened a crank or disc, with a fixed or moveable pin or an eccentric. To this movement one end of a connecting rod is attached, having a bush fitting into the crank or disc pin; or the connecting rod may have a strap to work on the eccentric as may be preferred. The other end of this rod is made to communicate with the arm of a pair of shears by means of an ordinary joint. These shears are similar, or somewhat similar, in shape to the ordinary hand shears at present used for cutting the edges of turf. An arrangement of one or more levers or screws is also provided for raising or lowering the shears as may be required, and also for placing them at any angle that may be found necessary when cutting. In working the implement it is simply moved or pushed forward by means of the guiding handles, when motion is communicated by the gearing to the shears, which cut the edges of the turf with precision. *Patent abandoned.*

1186. J. E. M'CONNELL and G. H. BOVILL. *Improvements in chains for cables and other purposes.* Dated May 11, 1863.

In carrying out this invention, the patentees propose to cast separately a number of detached links of the Bessemer iron or steel, or other suitable homogeneous metal, and then to connect these several links by casting intermediate or coupling links in moulds, into which two of the links are previously so placed as to enable the connecting link to be cast within or around them, and thereby producing three connected links. The end link of the series is then adjusted in a mould in company with another loose link, which latter is coupled or connected to the series by casting another connecting link within or around it. In this way the whole of the links of a chain are cast one within another without weakening the chain by welded joints. *Patent completed.*

1187. B. LILLY. *Improvements in the construction of "snap caps" or "nipple protectors" for firearms.* Dated May 12, 1863.

This invention consists in constructing the outer casing of the snap cap with a top or bottom, or with top and bottom sockets or chambers of suitable depths, so that the leather or other pad on which the gun-lock hammer falls can be securely fastened in the one, and a metal washer fitting the square of the gun nipple loosely secured in the other, while facility is also afforded for the introduction of a soft metal washer in conjunction with the pad in the top chamber, so as to interpose between the pad and the mouth of the gun nipple when the snap cap is in use. *Patent completed.*

1188. W. MATTISON and G. BARKER. *Improvements in grass-mowing and reaping machines.* Dated May 12, 1863.

The object of this invention is to simplify mowing and reaping machines, and to have the cutting apparatus and the gearing for giving motion thereto so constructed and arranged as to be self-adjusting to the irregularities of the ground; also to be readily raised or lowered, and put into or out of motion by the attendant. The cutting apparatus is mounted or carried on framing, which is hinged on bearings in the form of bushes fixed to the ordinary framing of the machine, concentric to the axle thereof, and so as to allow freedom of motion. A cog wheel is placed on the axle, capable of sliding into or out of gear with another wheel or a worm fixed on a shaft mounted on the moveable framing, on which is a crank for giving motion to the said cutting apparatus. The apparatus is raised or lowered, and the gearing put into or out of motion, by means of levers or equivalent appliances. *Patent abandoned.*

1189. T. WARREN. *Improvements in glass and other furnaces or kilns.* Dated May 12, 1863.

This invention is not described apart from the drawings. *Patent completed.*

1190. H. WICKENS. *Improvements in reaping and mowing machines.* (A communication.) Dated May 12, 1863.

The cutting apparatus of this machine is constructed and arranged to be worked on either side of the machine, and either in front or rear of the wheels, and the draught rod is arranged so that the line of draught may be taken from its inside shoe, or from its immediate vicinity. By these improvements the folding finger bar is sustained in the folded position while the machine is in motion from one place to another, and the gearing which drives the cutting apparatus is closed in for exclusion of dust and dirt. The inventor has an adjustable track board for disposing or controlling of the cut grass, and a means of turning the finger bar on its longitudinal axis, so as to elevate or depress the points of the guard fingers, which are constructed in a particular form at pleasure, without changing the relations of the bearings to each other at the two ends of the connecting rod. *Patent abandoned.*

1191. J. E. M'CONNELL and G. H. BOVILL. *Improvements in treating worn-out railway tyres.* Dated May 12, 1863.

This invention relates to modes of treating worn-out railway tyres, whereby, in place of breaking up the tyres as scrap iron, worn tyres may be manufactured into new tyres in hoops in a simple and economical manner. In carrying out the first part of this invention, it is proposed to take an old hoop tyre, say for a locomotive driving wheel, for example, and after heating it to the proper temperature to work the hoop through a suitable tyre-rolling machine provided with compressing rolls acting upon the outside of the red-hot hoop, whereby the diameter of the hoop is gradually reduced, and the thickness of the tyre increased in a corresponding ratio. The rolls are made to give the required form to the new tyre. The second part of the invention for manufacturing old hoop tyres consists in heating the old hoop tyre to a suitably high heat, and whilst in that state to place the same in a mould and pour into such mould around the outer face of the hoop molten homogeneous iron, Bessemer iron, or cast steel, to make up the required thickness of metal for the new tyre. *Patent completed.*

1192. W. WHITELEY. *Improvements in looms for weaving.* Dated May 12, 1863.

This invention relates to looms where two or more shuttles are employed, and consists in arranging and applying the mechanism or apparatus in conjunction with a jacquard machine, so that the loom will be self-acting in the production of the various figures or designs required in the fabric. The improvements have reference more particularly to the box motion of the loom, the shuttle boxes being acted upon by the lifting and sinking bars of the jacquard, which bars are made to project through the frame of the jacquard, and act upon hooks and levers connected directly to the shuttle boxes. By this mode of arranging the mechanism of boxes, they are raised or lowered as required by the jacquard itself, in place of the jacquard being made to govern a special mechanism for lifting the boxes. It is further proposed to adapt a reversing motion to the cylinder of the jacquard, whereby the shuttles are made to return to their former position without disconnecting the boxes and jacquard, and, consequently, their relative positions to each other are always maintained. *Patent completed.*

1193. G. A. HUDDART. *Improved apparatus for cutting slate.* Dated May 12, 1863.

This invention relates to cutting or dividing thick slabs or blocks of slate. The improved apparatus consists of a machine in which a cutting or planing tool of peculiar form or construction is made to pass over the slab and cut a deep groove therein. *Patent abandoned.*

1194. H. L. EMERY. *Improvements in apparatus for manufacturing saws suitable for ginning cotton and for other uses.* (A communication.) Dated May 12, 1863.

This invention is not described apart from the drawings. *Patent completed.*

1195. R. A. BROOMAN. *Improvements in spring mattresses.* (A communication.) Dated May 12, 1863.

The chief object of this invention is to construct spring mattresses which can be taken to pieces when required and packed into a small space for removal or otherwise. The frame of the mattress may be made of wood or iron. The construction, when the frame is of wood, is as follows:—Two boards or planks forming the sides of the mattress carry brackets for receiving two other boards or planks for the ends; transverse bars strengthen the sides and carry spiral or other springs. The ends are connected to the sides by bolts and nuts, which bolts pass through the brackets. Transverse planks are fixed on the ends, pegs are fixed on these planks, to which laths or flat chains passing from end to end of the mattress are hooked; these chains pass over and are sustained by the springs which are supported by the first-mentioned transverse bars, and are strengthened by other transverse laths. To take to pieces a mattress constructed as before described, it is only necessary to unhook the laths and to unscrew the bolts and nuts. *Patent completed.*

1196. R. A. BROOMAN. *Improvements in spring mattresses, sofas, chairs, seats, and similar articles.* (A communication.) Dated May 12, 1863.

This invention relates to those mattresses, sofas, chairs, seats, and similar articles in which springs are employed, and has mainly for its object the fastening of the springs without the aid of strings, of sewing, or of nails as hitherto. At each corner of a frame of laths or plates the inventor fixes a vertical tube, and at each corner of a similar frame he fixes a vertical rod. He places one frame upon or over the other so that each of the vertical rods may enter one of the vertical tubes, and he retains the rods in the tubes by nuts, or by grooves formed on the tubes. He places helical or other springs between the two frames, and fixes them by means of claws formed on the laths or plates by a suitable tool or otherwise. Upon a person lying or sitting on the mattress or other article, the springs will be compressed, and the upper frame will descend to an extent proportionate to the weight it bears; and when the person rises the springs and upper frame will resume their original position. Or he forms mattresses, seats, and other articles of two boxes or cases without bottoms, one of which is free to slide in the other and retained therein by flanges; one of the boxes also carries flanges for supporting two frames of laths or plates between which the springs are held. The extent to which the upper box is permitted to descend upon a weight being put upon it, may be regulated by forming grooves in one box and corresponding projections upon the other box. He prefers to form the tubes employed as before described, in two parts, by cutting and stamping, and to connect the two parts by screws, rings, or otherwise. *Patent abandoned.*

1197. R. A. BROOMAN. *Improvements in machinery for preparing, dressing, and winding cotton, woollen, flax, silk, and other warps.* (A communicat[illegible] [illegible]ted May 12, 1863.

The characteristic features of th[illegible] the carrying on in one machine of [illegible] of taking the threads from the bobb[illegible] ing or winding on the warp beam; 2, [illegible] rangement of the racks or nests with [illegible] niding the threads and a brake com[illegible] 3, the gathering plate; 4, the a[illegible] ng cylinders with variable pres[illegible] f the revolving brush with in[illegible] drying or fanning of the t[illegible] r-forated with holes. The [illegible] ng machinery for preparing [illegible] on, woollen, flax, silk, and [illegible] described. *Patent compl[illegible]*

1198. H. RUSHTO[illegible] *[illegible]sses.* Dated May 13, 1863.

In carrying out [illegible] tw puffs, rolls, or ro[illegible] ed [illegible]

woven hair, intermittently at one end in a point; these points he connects by a piece of elastic material; the puff rolls are made to swell gradually from the pointed or upper ends, and then diminish toward the lower ends, where he also connects them by a piece of elastic material, thus forming an expanding circlet or band for the head, which instantly fixes itself in any required position thereon. To complete the said head dress, to the lower parts of the expanding puffs he attaches hair ringlets or roll curls, and when placed upon the head the front hair is turned back, over, and round the puffs, and fastened at the back; the artificial curls fall behind the ears, and thus form an elegant finish to the whole. *Patent abandoned.*

1199. R. A. Brooman. *Improvements in laying submarine telegraph cables.* (A communication.) Dated May 13, 1863.

This invention consists in connecting to the cables, as they leave the vessel from which they are paid out, buoys fitted as hereafter explained, and which, after a certain time, lose their buoying properties, whereby a nearly constant tension is maintained on the cable. In addition to the buoys, in some cases heavy weights are attached to cause the cable to descend to the bottom of the water in which it is being submerged. The buoys are, by preference, in the form of balloons of caoutchouc, or waterproof cloth, and when not extended occupy little space in the vessel. These buoys are provided with a tap, in which there are two ways, one for the admission of air, and the other closed by wire gauze for the escape of air; the wire gauze is covered by gum or other material which will dissolve after exposure to the water; and according to the nature and thickness of this covering, so will the air escape more or less quickly after the balloons have been submerged. The balloons are attached to a cord, the lower end of which carries a weight, and as the cable is leaving the vessel the balloons are attached by throwing or twisting the weighted end of the cord round it. Instead of balloons, or together with balloons, buoys in the form of parachutes may be connected to the cables in a similar manner to the balloons. *Patent completed.*

1200. H. Wilde. *Improvements in electro-magnetic telegraphs.* Dated May 13, 1863.

This invention consists of improvements in the indicating instrument described in the specification of letters patent granted to the present patentee April 8th, 1861, No. 858. In the indicator therein described, a revolving index is made to point successively to letters engraved upon a stationary dial. In the present improvement the dial, instead of being stationary, is made to revolve, and before it a magnifying glass or microscope of suitable size is so placed as to cause only the required letter on the revolving dial to be visible to the person receiving a message when the dial stops. *Patent completed.*

1201. T. Parkinson. *Improvements in machinery for weaving, sizing, dressing, and dyeing.* Dated May 13, 1863.

This invention consists—1, in certain improvements in the letting-off motion of looms for weaving; and 2, in agitating liquids employed in sizing, dressing, and dyeing by means of a screw revolving in the vessel containing the liquid. The invention cannot be described without reference to the drawings. *Patent completed.*

1202. F. Holthausen. *An improved portable copying press.* Dated May 13, 1863.

In carrying out this invention, the inventor constructs a strong rectangular box, open at one or both ends, and rather larger in length, breadth, and thickness than the book in which the letters or other papers are to be copied. A screw furnished with a winch-handle is mounted longitudinally in bearings fixed to the lower side or bottom of the box, and carries a screw nut, which, as the screw is turned, slides in a mortise formed in the centre of the bottom of the box, the said mortise forming a guide for the said screw nut. Inside the side box is placed a loose plate of iron or hard wood provided with a wedge, which is of the same size as, and fits into, the aforesaid mortise, the thin end of the wedge being immediately in front of the screw nut when in its normal position. This wedge is divided longitudinally in the middle to leave room for the screw. It will be evident that, upon turning the screw by means of the winch-handle, the screw-nut will be caused to advance, and, acting upon the wedge, will cause the loose plate to rise and exert a corresponding pressure upon the book or other article that may be placed between it and the top of the box. A metal plate covering the mortise is secured on to the bottom of the box below, serving as a point of resistance to the screw-nut, which rests on it, and thus preventing the bending downwards of the screw by the pressure. *Patent abandoned.*

1203. J. E. M'Connell and G. H. Bovill. *Improvements in the manufacture of thick plates of wrought iron for armour plates and other purposes.* Dated May 13, 1863.

This invention is not described apart from the drawings. *Patent completed.*

1204. V. J. Cassaignes. *Improvements in stereoscopes.* Dated May 13, 1863.

This invention consists in colouring the prisms or lenses of stereoscopes so that each prism or lens presents several different tints or colours, and so that, consequently, the pictures or images seen through these glasses will appear under different aspects, giving, for example, the effects of morning, or of the sunrise, or of moonlight. *Patent completed.*

1205. C. L. Kensner. *Improvements in the manufacture of hydrate of barytes, and in the manufacture of sugar.* Dated May 13, 1863.

In order to manufacture hydrate of barytes suitable for being used in the manufacture of sugar, as hereafter described, carbonate of barytes is decomposed by subjecting it mixed with coal or charcoal, and a small quantity of a suitable flux (for which it is preferred to use an alkali or an alkaline earth) in an air or reverberatory furnace to a temperature commencing with about 800 degs. of Fahr., and raising the temperature up to a white heat. The charge is then to be drawn into a suitable receiver, and allowed to cool in the open air. When cool the charge is turned out the vessel; and water is to be gradually applied so as to slake the product, taking care not to apply too much water till the whole of the charge is slaked, when the charge is to be dissolved in water, and the solution, after being allowed to settle for a time, is fit to be employed in the manufacture of sugar as hereafter described. In order to obtain sugar from molasses, treacle, and other saccharine fluids, a solution of hydrate of barytes is mixed therewith, whereby a precipitate is obtained, which precipitate is to be mixed with water to which carbonic acid is to be applied in order to convert the barytes into a carbonate, which will precipitate and leave a syrup suitable to be treated in the ordinary manner to obtain crystals of sugar therefrom. *Patent abandoned.*

1206. B. Lambert. *Improvements in paper makers' rag or pulp engines.* Dated May 13, 1863.

For the purposes of this invention, in order more effectually and advantageously to carry off the water from a rag or pulp engine, a hollow partition is applied on the flow side of an engine, which divides the stream or flow of the stuff in the engine into two streams. The sides of the hollow partition are formed of sheet metal perforated with numerous holes, or of other suitable reticulated or perforated material. In addition to such hollow perforated partition, the side of the midfeather end of the engine or the flow side may, as has heretofore been proposed, be hollow and made suitable for straining off the water. In order more effectually to boil the stuff in a rag or pulp engine, provision is made for preventing the flow of air under the cover and above the stuff in the engine, which is ordinarily caused by the action of the breaking roller of the engine. This is effected by means of an axis or roller, having radial float boards, which axis or roller is above the fluid in the engine. At the end of the cover of the engine a flexible or yielding curtain is so arranged that the float boards which, as they revolve, dip into the stuff, are caused to move at a somewhat quicker speed than the flow of the stuff in the engine, whilst the air is prevented flowing under the cover and between it and the stuff by the float boards or paddles which are above the fluid, coming in succession against the flexible or yielding curtain. *Patent completed.*

1207. A. G. Southey. *Improvements in railway roof lamps, station, signal, and other fountain lamps.* Dated May 13, 1863.

This invention consists in adapting the above-named lamps to the use of the heavier portion of oils by means of a chimney supported over the flame, the lower edge of which is made to act as a deflector. *Patent abandoned.*

1208. J. Farmer. *Improvements in calendering, embossing, and other such machines used for finishing woven fabrics, part of which is applicable to drying machines.* Dated May 13, 1863.

This invention is not described apart from the drawings. *Patent completed.*

1209. R. A. Brooman. *Improvements in the extraction of hydro-carburets from minerals in the distillation thereof, and in apparatus employed therein.* (A communication.) Dated May 13, 1863.

This invention relates to the extraction of hydro-carburets from mineral matters containing the same. The process of distillation is based upon—1, the generation of steam (as described); 2, its mode of action—that is to say, the perfect stability of its caloric, and its speed uniformly distributed (as described); 3, the volume of dry or desaturated steam (4,180 volumes for 1 volume of water), which produces quantities of oil in proportion to the space occupied by the steam; and 4, the employment of hydrogen and oxide of carbon for heating the retorts or coils, by which means the caloric is uniformly distributed, and may be increased or diminished by means of a tap, and by which the steam is allowed as long a course as may be necessary under the same conditions of heat, the loss produced by radiation being obviated, all as hereafter described. The steam gathers in its passage a quantity of oil in proportion, not to the quantity of the steam, but to the space passed over by it. The apparatus for carrying out this invention is constructed with the object of obtaining the greatest possible extent (longevité) of action of the steam on the matters under treatment on the one hand, and on the other to equalize its speed at all points, so that the calorific properties brought by the steam having to undergo no diminution nor increase in speed there shall be thermometric identity from the time of its admission up to the time of its exit, and that the cooling due necessarily to the work of the steam shall be uniformly spread over the whole apparatus; the loss of heat is easily compensated for by means of inflamed hydrogen, the quantity of which should be varied in direct ratio to the initial velocity of the steam. *Patent completed.*

1210. T. Lawrence. *Certain improvements in machinery or apparatus used in the processes or operations of drying, dressing, brushing, waxing, and finishing fabrics.* Dated May 14, 1863.

This invention consists—1, in an improved arrangement and combination of rollers and chambers heated by hot air or gas for drying fabrics; 2, in the application of a revolving bed heated by an admixture of air and gas for dressing or ironing fabrics; 3, in an improved arrangement and combination of a revolving disc containing wax with helically-formed revolving peg rollers and brushes for brushing, waxing, and finishing fabrics. *Patent completed.*

1211. J. Satchwell, W. H. Ashford, and C. Harrison. *Improvements in nails or rivets for boots and shoes, applicable to other purposes.* Dated May 14, 1863.

This invention consists in making from a round piece of wire a rivet with a raised head and threaded shank. Though applicable for other purposes the inventors design them as especially useful in the manufacture of boots and shoes, the soles and heels of which have hitherto been first united by means of nails with a flat or countersunk head, and rivets have been afterwards driven in. Now, by this invention, they construct such a nail or rivet as above described as to combine the two, so as to render one operation only needful where formerly two were necessary. *Patent abandoned.*

1212. A. Pilbeam. *Improvements in sewing machines.* Dated May 14, 1863.

This invention is not described apart from the drawings. *Patent completed.*

1213. J. T. King. *Improvements in wicks for oil and other fluid burning lamps.* (A communication.) Dated May 14, 1863.

This invention consists in placing within an outer covering of woven fabric, or other flexible material, a quantity of loose or unwoven cotton, flax, rhea fibre, grass, or any other fibre or fibrous material, preferably combed, drawn, or worked into its or their greatest length or lengths, so that the power of raising the fluid in the container of the lamp to the point of combustion by capillary attraction may be increased. *Patent abandoned.*

1214. J. Burrell. *Improvements in the construction of cocks or valves.* Dated May 14, 1863.

In constructing cocks or valves according to this invention, a conical shell is employed, which, at its larger end, is made to adapt to the supply pipe or nozzle, and in the side of the shell is the outlet orifice for the passage or passages for the fluid to pass away from the cock or valve. Within the shell is a hollow plug turned and ground to fit it truly; this plug is open at its larger end for the fluid from the supply to enter it; at its smaller end it is closed, and this end projects out at the extremity of the shell, and receives a handle by which the plug may be turned, and by turning it, an opening in the side of the plug can be brought to correspond with the outlet passage in the shell. It will be seen that in this arrangement the pressure of the fluid in the supply pipe or vessel tends to press the plug into its seat in the shell and to keep it tight. *Patent abandoned.*

1215. G. Dowler. *An improvement or improvements in match boxes.* Dated May 14, 1863.

This invention consists in constructing match boxes with a spring striker on either the top, bottom, or end of the box. *Patent abandoned.*

1216. L. C. Chichester. *Improvements in machinery for weighing grain.* Dated May 14, 1863.

This invention consists—1, in a mode of hanging a swinging bucket that receives the grain, and tips the same out by swinging on its centres, and then swings back again to receive a fresh supply of grain; 2, in a mode of fitting a series of weights so that they shall be successively and gradually raised as the weight of grain causes the said bucket to descend, thereby avoiding any sudden motion or shock of the parts; 3, in an arrangement of cut-offs that check and finally stop the flow of grain from a hopper or spout into the bucket as the said bucket descends in consequence of the weight of grain deposited in such bucket; 4, in a peculiar construction of delivery-mouth at the lower end of the hopper or spout to arrest the momentum of the grain, and thereby ensure accuracy in the weighing operation, because the impetus of the descending grain is checked before reaching the scale; 5, in a peculiar catch for holding the bucket while being filled. The invention cannot be described without reference to the drawings. *Patent completed.*

1217. F. K. Eblam. *A new lubricating material or compound.* Dated May 14, 1863.

The inventor proposes, in the first place, to apply the material, known as plumbago or carbonate of iron, reduced to a state of impalpable powder. He also forms a compound by admixture of plumbago or carbonate of iron with prepared chalk, or the substance commonly known as French chalk. *Patent abandoned.*

1218. G. T. Bousfield. *Improvements in machinery for rolling, grinding, and cutting files and rasps.* (A communication.) Dated May 14, 1863.

This invention is not described apart from the drawings. *Patent completed.*

1219. I. Parker. *Improvements in connecting and securing door and other knobs or handles to their spindles.* Dated May 14, 1863.

In carrying out these improvements, the patentee takes a spindle screwed from end to end with a suitable screw, the sides being squared down, as is well known and practised with door spindles of other constructions. He uses door knobs or handles of ordinary and well known shapes and materials, and upon one of such knobs or handles (which by preference he places outside the door) he fixes a plate of brass, or other suitable metal or material, which plate is perforated with one or more holes (or such holes or recesses may be formed in the knob or handle itself when made of suitable material) towards its outer edge, and having a central hole screwed inside into which the spindle screws as far as required. Sliding on the spindle by means of a square hole, but not turning round thereon, is a loose plate of suitable thickness, and (by preference) of the same diameter as the plate attached to the knob; and in the body thereof, towards the outer edge, there are one or more studs or pins which take into and fit the hole or holes in the door knob or handle. Other means may be adopted for catching or locking this plate to the plate fixed on the door handle or knob; but he prefers to employ the means above described. On the other knob or handle, which he places by preference inside the door, a plate of brass or other suitable metal or material is fixed as before; but instead of a hole or holes in such plate or knob (when the plate forms part of the knob), a square or oblong stud is fixed, which stud is made by preference of the same size as the square on the spindle. A plate or disc is attached to this knob, which plate or disc is cut nearly across by a slot of similar width to the square of the spindle, and at one end of the slot a round opening is formed wherein the spindle revolves when required, and when in position it slides on the square stud above referred to. When fixing the knob on to the spindle, the plate is slid sideways till the spindle revolves in the circular part of the slot, and the knob is screwed as far on as may be required; the plate is then pressed down on the stud until it comes to be concentric to the plate on the knob, when the slot then fits the square on the spindle, and causes the spindle to turn round on moving the knob or handle. The plate may be secured to or prevented from sliding upon the knob by means of a cover plate screwed on the door, or by set screws, or other suitable means. *Patent completed.*

1220. B. Shillito and D. Moor. *Improvements in generating heat and motive power.* Dated May 15, 1863.

In carrying out this invention, the patentees so form the furnace as to burn off the fuel within an air-tight enclosure, and force in, under the requisite pressure, the amount of atmospheric air necessary for effecting the combustion of the fuel. They regulate the emission or escape of the products of combustion from the furnace and flues or passages by means of a valve, damper, or regulator, or by valves, dampers, or regulators, capable of being closed air-tight: and the hopper-door, or other means of admitting the fuel into the furnace, is closed air-tight, to resist the requisite pressure. *Patent completed.*

PROVISIONAL PROTECTIONS.

Dated November 5, 1863.

2739. R. Smith, Glasgow, manufacturing chemist. Improvements in preparing or obtaining colouring matters.

Dated November 9, 1863.

2786. R. H. Philipson, agent, and J. Dees, engineer, Cassop, Durham. An improved machine adapted for performing various mining operations, such as working or cutting coal or other analogous substances in mines, forcing water from mines, and air thereunto.

Dated November 14, 1863.

2846. E. Hargraves, Manchester. Improvements in preventing the escape of heat from steam boilers and other heated surfaces.

2857. J. Harrison, Kingston-upon-Hull, seed crusher. Improvements in mills for cleaning cotton seed.

Dated November 16, 1863.

2862. J. Hulse and J. Lawrence, Willenhall, Stafford, wood turners. An improved mode of attaching door knobs to their spindles.

2867. E. W. Elmslie, Great Malvern, architect. An improved and economical construction of cottages, applicable also to various other descriptions of buildings.

Dated November 19, 1863.

2898. J. Elder, Glasgow, engineer. Improvements in steam engines.

2901. I. Francis, Pen-y-gelli, near Wrexham. Improvements in, and apparatus for, washing, cleaning, and separating impurities from small coal, coke, ashes, or cinders.

2903. J. Kirkham, Euston-road, civil engineer. Improvements in the treatment of certain ores of iron.

2904. E. Walker, London-street, windlass manufacturer. Improvements in windlasses.

2905. J. Collyer, Leman-street, Whitechapel, manufacturing cooper. Improvements in the mode of, and apparatus for, stopping or closing orifices in casks and other vessels.

2906. R. and J. S. Walker, Bury, machinists, and B. Brown, mechanic. Improvements in machinery for preparing cotton to be spun.

2907. E. Christmas, Watford, Hertfordshire. Improvements in carriages.

2908. W. Symons, 17, St. Mark's-crescent, Regent's-park, philosophical instrument maker. Improvements in the construction and working of railways.

2909. B. Gooch, 4, Bridge-street, Westminster. Improved wrought-iron sheeting piles.

2910. J. Colling and D. G. Pinkney, Seaham, Durham, master mariners. Improvements in apparatus for reefing and furling ships' square sails.

2911. W. B. Hodson, Cotton-street, Bow-common, metallic cask maker. Improvements in the manufacture of metal drums and cans for holding oils and other fluid matters, and in furnaces used in such manufacture.

Dated November 20, 1863.

2912. G. Rait, Canal-bridge, Kingsland-road, managing director of the Gas Meter Company, and J. Winsborrow, 23, Castle-terrace, Pownal-road, Dalston, foreman. Improvements in the construction of dry gas meters, and in the means or apparatus employed therein.

2913. J. Seward, Clitheroe, Lancashire, and H. Smith, Enfield. An improved apparatus for preventing incrustation in steam boilers.

2914. E. Marwood, Blackburn, cork manufacturer. The application of a certain substance or material for covering rollers used in spinning and preparing cotton, wool, and other fibrous substances to be spun.

2915. B. Dodson and E. Barlow, Bolton, machine makers, and P. Knowles, foreman. Improvements in machinery for ginning cotton and for opening cotton and other fibrous substances.

2918. A. H. Ferry, merchant, 2, Rue Ste. Appoline, Paris. Improvements in making hammers for pianofortes.

2919. J. J. Hays, Hitchin. Improvements in hot-air stoves.

2920. G. S. Kirkman, 27, Claremont-terrace, Fentiman's-road, civil engineer. Improvements in apparatus used for connecting railway carriages and trucks.

2921. T. Brinsmead, St. Giles-in-the-Wood, near Torrington, Devon. Improvements in apparatus for thrashing and reeding wheat and other straw.

2922. A. McLaine, Belfast, ship builder. Improvements in the construction of gun boats, gun vessels, and rams.

2923. G. Fawcus, North Shields, shipbuilder. Improvements in connecting scaling, firing, and other like ladders.

2924. W. E. Newton, 66, Chancery-lane, civil engineer. Improvements in the construction of fan blowers for ventilating and other purposes. (A communication.)

2927. J. H. Johnson, 47, Lincoln's-inn-fields, gentleman. Improvements in steam engines and in apparatus connected therewith. (A communication.)

Dated November 21, 1863.

2928. C. E. Wright, Colville-terrace, Sherwood-street, Nottingham, mercantile traveller. Improvements in apparatus for clipping or binding together letters, music, and other loose sheets.

2929. T. Turner, Glasgow, architect and civil engineer. An improved fire-proof floor or roof for buildings, bridges, and other structures.

2931. F. Fenton, Camberwell. Improvements in the treatment of vegetable fibres for the production of paper pulp or half stuff therefrom.

2932. W. Williams, Stanley, Liverpool, brickmaker. Improvements in machinery for making bricks and other like articles.

2933. D. Cope, Liverpool, oil merchant. Improvements in the manufacture of metallic drums, kegs, casks, and like cylindrical packages.

2935. E. Finch, Bridge Works, Chepstow. Improvements in constructing the floors of bridges, houses, and other buildings.

2936. F. Watkins, London Works, near Birmingham. Improvements in machinery for the manufacture of bolts, nuts, spikes, and rivets, and also in furnaces for heating blanks to be formed into such articles.

2939. D. W. Hamper, Newcastle-upon-Tyne, brewers' engineer. Improvements in apparatus for mashing malt for brewing or distilling.

2940. M. B. Westhead, Manchester, manufacturer and merchant. Improvements in adapting or arranging tapes and other such narrow fabrics and threads for use.

Dated November 23, 1863.

2942. W. Bestwick, Manchester, braid manufacturer. Improvements in braiding machines.

2944. P. Bawden, Queen-street, Cheapside. Improvements in machinery for making bricks.

2945. J. Smith, Liverpool, painter. An improved composition for coating or covering the bottoms of ships.

2946. E. B. Wilson, 10, Strand, engineer; and J. Imray, 190, Westminster-bridge-road. Improvements in presses.

2947. T. Carr, New Ferry, near Birkenhead, engineer. Improvements in machinery for amalgamating or intermixing, dry, semi-fluid, or aqueous materials, and for agitating solids with liquids for combining, dissolving, or washing the same.

Dated November 24, 1863.

2949. G. W. Yapp, 16, Clement's-inn. Improvements in the preservation of animal substances. (A communication.)

2951. D. W. Rea, Upper Thames-street, provision merchant. Improvements in preserving animal and vegetable substances.

2952. W. Howlett, 16, Cottage-grove, Mile-end-road, commercial clerk. Improvements in printing floor cloths, carpets, and similar goods, and in the machinery or apparatus to be employed therein.

2954. G. Davies, 1, Serle-street, Lincoln's-inn, civil engineer. Improvements in photography. (A communication.)

2955. J. Lewis, 5, Wych-street, Strand, engineer and model maker. Improvements in driving sewing machines, which improvements are also applicable for driving other machinery.

2956. J. H. Johnson, 47, Lincoln's-inn-fields, gentleman. Improvements in rotary engines. (A communication.)

2957. R. Furnival, Manchester, machinist. Improvements in braiding machines.

2958. W. E. Newton, 66, Chancery-lane, civil engineer. Improvements in machinery for breaking and cleaning flax, hemp, and other fibre-yielding plants. (A communication.)

2959. W. E. Newton, 66, Chancery-lane, civil engineer. Improvements in balloons or aeronautic apparatus. (A communication.)

2960. J. Sibert, 9, Carter-gate, Nottingham. Improvements in the manufacture of joined blond, and in the machinery employed therein.

2961. P. Tait, Limerick, Ireland. Improvements in apparatus used for pressing and ironing garments.

2962. C. L. Daboll, Aldersgate-street. Improvements in marine fog signals or alarums.

Dated November 25, 1863.

2963. G. Parkin, Tryddyn, engineer. Improvements in apparatus employed in the manufacture of paraffine and other like oils from shale, cannel, and other like minerals.

2964. T. Wilson, Birmingham, mechanical engineer. Improvements in presses for cutting, perforating, and shaping metals.

2965. M. Power, Worcester, head constable of City Police. Improvements in fire-escapes.

2967. L. Accarain, Mons, Belgium, merchant. Improvements in the manufacture of paper, thread, cordage, and fabrics from beetroot.

2968. J. H. Wilson, Liverpool, brass founder and ships' ironmonger. Improvements applicable to ships' and other lift pumps.

Dated November 26, 1863.

2969. H. B. Barlow, Manchester. Certain improvements in looms for weaving. (A communication.)

2970. D. Kircaldy, Glasgow, engineer and draughtsman. Improvements in testing or measuring the strength and other properties of various materials and structures, and in apparatus therefor.

2971. R. Laming, Priory-road, Kilburn. Improvements in preparing materials useful in the purifying of gas from sulphuretted hydrogen, carbonic acid, and ammonia, and in making ammoniacal compounds.

2972. J. Thorpe, Whittle's Croft, London-road, Manchester, manufacturer. Improvements in the mode of marking patterns or designs upon gored and straight skirts and skirtings to serve as a guide for sewing and embroidering thereon.

2973. J. Simmonds, Holland-street, Clapham-road, plumber. Improvements in stink traps for water-closets, sinks, and other purposes.

2974. J. Baker, Temple-street, Whitefriars. Improvements in compositions applicable to the coating of ships' bottoms.

2975. J. Nadal, 14, Brooke's-market, Brooke-street, Holborn. Improvements in apparatus for raising and forcing fluids.

2976. J. S. Jarvis, Wood-street, City, warehouseman. An improved shirt collar.

2977. J. Ulsterman, Sheffield, manufacturer. Improvements in frames for umbrellas and other like articles, and petticoats or skirts.

Dated November 27, 1863.

2979. W. C. Brocklehurst, Macclesfield, silk manufacturer, and J. and J. Creighton, Manchester, machinists. Certain improvements in machinery or apparatus for winding yarns or threads.

2980. T. Gray, Mitcham, bleacher. A new method of discharging colour from rags used for paper-making or other purposes, and in the treating of vegetable fibres by such process.

2981. F. Page, Birmingham, bank accountant. Improvements in furnaces and apparatus for the manufacture of volatile hydro-carbons, which improvements are also in part applicable to furnaces and apparatus for the manufacture of illuminating gas.

2982. J. B. and D. Bateman, Bradford. Improvements in sewing machines.

2983. C. Crabtree, Bingley, Yorkshire, spool tube manufacturer. Improvements in the manufacture of paper spool tubes.

2984. J. Clark, Manchester, airproof and waterproof fabric manufacturer. Improvements in looms for weaving elastic fabrics.

2985. J. Clark, Manchester, airproof and waterproof fabric manufacturer. Improvements in machinery or apparatus for cutting strips or threads of india rubber or other materials.

2986. E. Gardner, Manchester, loom maker and machinist. Improvements in looms for weaving elastic fabrics.

2987. H. Hirzel, doctor of philosophy, and lecturer on chemistry and pharmacy, Terminus Hotel, London-bridge. Improvements in extracting essences and perfumes and also oils and fats from matters containing them, also in bleaching and purifying oils and fats, and in apparatus employed therein.

2988. S. and T. Smith, 5, Fell-street, City, wholesale confectioners. Improvements in composition or means for the purpose of destroying insects by fumigation and in means or apparatus employed therewith.

2989. P. Gaskell, Walsall-road, Birmingham. Improvements in tell-tales or indicators for cabs and such like public vehicles.

Dated November 28, 1863.

2990. E. Bevan and W. S. Weare, Birkenhead, watch-manufacturers and copartners. Improvements in and applicable to watches to obtain or produce independent centre seconds.

2991. C. Cordon, Nottingham, plumber. Improvements in means or apparatus for supplying water to water-closets and urinals.

2992. E. Ironmonger, 1, Friar-gate, Derby, auctioneer, upholsterer, and furniture dealer. Improvements in the means of fitting together or connecting articles or parts of articles.

2993. T. Lane, Cirencester, implement maker. Improvements in chaff-cutting machinery.

Dated November 30, 1863.

2994. A. Etienne, Great Portland-street, Oxford-street. Improvements in the construction of carriages and vehicles, and of wheels applicable thereto.

2995. A. Albini, Birmingham, Captain in the Italian Navy. Improvements in ships of war and in arming ships of war.

2996. G. A. and G. A. Thompson, upholsterers, and J. Latham, patent lock maker, Birmingham. Improvements in the manufacture of door springs, part of which said improvements are applicable to the manufacture of weighing machines, steelyards, scale beams, and other articles of like nature.

2997. W. Campion and G. Wilson, machine builders, and A. Wilson, hosiery manufacturer, Nottingham. A new or improved self-acting time register.

2999. J. Chalmers, 5, Wellington-road, Kentish-town. Improvements in guns and gun projectiles.

3000. E. W. James, Brynllys, near Aberystwyth. Improved apparatus for drilling or boring rock and other earthy substances, for exploring and other purposes.

3002. J. M. Ollis, Plymouth, chief engineer. Improvements in apparatus for obtaining fresh water from sea water.

3003. C. Pontifex, St. Paul's-road, Islington, vat and back maker and patent refrigerator manufacturer. Improvements in the construction of sluices and other cocks or valves, and in the means of connecting them and the ends of flexible hose pipes together.

3004. J. E. and E. H. Blundon, Fleet-street, portmanteau and travelling-bag manufacturers. Improvements in the construction of letter, tourist, despatch, and other similar bags or receptacles.

Dated December 1, 1863.

3005. E. M. Boxer, Royal Arsenal, Woolwich, Lieut.-Colonel Royal Artillery. Improvements in fuses and shells for ordnance.

3006. H. Wilde, Manchester, engineer. Improvements in the construction and working of electric telegraphs, and in apparatus connected therewith, partly applicable to other purposes.

3007. P. G. Gardiner, New York, United States. An improvement in railroad car springs.

3008. R. Brailsford, Knowsley, Lancashire, trainer of dogs. Improvements in the construction of vermin traps.

3009. B. Jones, Warrington, manufacturing chemist. Improvements in separating sulphur from alkali waste.

3010. G. J. Doddrell, Glasgow, North Britain, sugar refiner. Improvements relating to the manufacture or refining of sugar.

3011. W. E. Gedge, 11, Wellington-street, Strand. Improved plough. (A communication.)

3012. J. G. Redman and G. Martin, Brompton ... provements in compounds or compo itions for coa... covering iron or wooden ships and vessels, metallic ... ing, telegraph cables, and other objects, to prese... from decay, fouling, or other destructive action.

3013. H. Lumley, Chancery-lane, Associate of th... tution of Naval Architects. Improvements in a... for steering.

3014. R. Turnbull, Portsmouth, shipbuilder. Improvements in sheathing iron vessels and armour-plated ships.

3015. W. Clark, 53, Chancery-lane, engineer. Improvements in apparatus for lighting and heating. (A communication.)

3016. E. A. Inglefield, Her Majesty's ship "Majestic," Captain in the Royal Navy, F.R.S. and F.R.G.S. Improvements in apparatus for mounting and working guns used in ships and other floating vessels, and in fortifications.

3017. G. Glover, Ranelagh Works, Ranelagh-road, Pimlico. Improvements in dry gas meters.

3018. J. Thom, Hull, mechanic. Improvements in apparatus to be employed in expressing oils and fatty matters.

3019. T. Mallinson, Globe Works, Manchester, machine maker. Improvements in certain self-acting mules for spinning and doubling cotton and other fibrous materials.

3020. S. B. Cochran, 9, Catherina-terrace, Lansdowne-road, Clapham-road, machinist. Improvements in sewing machines, and in apparatus connected therewith.

Dated December 2, 1863.

3021. G. Macfarlane, Draycott-street, Chelsea, professor of music. A new and improved ink regulator and indicator.

3023. W. Wilson, Manchester, ironmonger. Improvements in generating gas for illuminating and other purposes, when made by passing atmospheric air over or through volatile oils, and treating such gas and the gas made from coal or cannel, after leaving the generators, so as to improve the heating and illuminating qualities thereof, and in the apparatus for effecting the same.

3027. A. W. Haley and A. Bingham, engineers and machinists, and R. Webster, mechanic, Manchester. Improvements in machinery or apparatus for making envelopes and other similar purposes.

3031. J. Harper, Aberdeen, fence maker. Improvements in pillars and apparatus for straining wire.

3033. J. Cutler, Gloucester-road, Upper Holloway. Improvements in apparatus for lighting and ventilating.

PATENT APPLIED FOR WITH COMPLETE SPECIFICATION.

Dated December 5, 1863.

3059. H. A. Bonneville, 24, Rue du Mont Thabor, Paris. Improvements in fret saws.

NOTICES OF INTENTION TO PROCEED WITH PATENTS.

From the *London Gazette*, December 15, 1863.

1884. J. W. Branford. Agricultural implement.
1901. W. Cotton. Looped fabrics.
1910. T. Fellowes and H. Hempey. Apparatus for elevating straw.
1911. J. E. Vanner. Umbrellas and parasols.
1928. E. A. Cowper. Furnaces.
1929. G. Clark. Construction of ships.
1931. W. Storer and J. Hancock. Electromotive engines.
1933. W. Hodson. Propelling carriages and vessels.
1937. J. E. Dowson. Rolled metal plates.
1940. J. Fenwick. Self-acting valves.
1941. J. Young. Preservation of animal matter.
1942. W. Clark. Ovens. (A communication.)
1944. G. E. Charageat. Frames for umbrellas.
1945. E. E. Quelle. Inkstands.
1946. J. Kirkham. Apparatus for generating heat.
1947. T. Simmelkiar and J. I. Spicer. Composition for the bottoms of ships.
1949. W. Jones. Steam boilers.
1951. A. V. Newton. Shuttles. (A communication.)
1952. J. W. Slater. Yellow and orange colouring matters.
1957. T. W. Guillod. Chessboards and chessmen.
1959. J. Thompson, E. G. and F. A. Fitton. Engines for carding cotton.
1960. N. Jarvie and W. Miller. Oakum.
1964. H. R. Brown. Apparatus for the regulated delivery of cards, tickets, labels, &c.
1965. M. Smith. Obtaining farinaceous material from potatoes.
1966. J. W. Armstrong. Securing the rails of railways.
1967. J. A. Fullarton. Fastening hoops for packing bales.
1970. R. Dickson. Lithographic printing presses.
1976. W. Knowles and R. Halliwell. Spinning and doubling cotton.
1982. W. Clark. Road sweeping machines. (A communication.)
1983. J. Wheeler. Perfuming of gloves.
1991. J. Templeman. Artificial fuel.
2010. R. B. Greenwood. Preventing accidents upon railways.
2016. N. S. Russell. Working great guns.
2017. J. Wain. Doubling or twisting yarns.
2037. A. M. Dearn. Mashing machine.
2045. J. Arthur. Apparatus for the cure of hernia.
2052. R. A. Brooman. Hats, caps, and bonnets. (A communication.)
2053. R. A. Brooman. Treating molasses, syrups, &c. (A communication.)
2096. F. R. Stack. Military bridges, piers, &c.
2126. E. Amoureus. Separating solid from fluid fecal matters.
2159. W. Clark. Hydraulic apparatus. (A communication.)
2177. N. Bailly. Application of rolling friction to axle-boxes. (Partly a communication.)
2201. A. V. Newton. Directing motion in right lines. (A communication.)
2214. J. Lillie and J. H. Waite. Preservation of surfaces of iron, wood, and other materials.
2229. J. H. Wilson. Side lights for ships.
2287. P. McLaurin. Drying paper.
2293. I. Baggs. Preserving the hulls and bottoms of ships.
2621. A. V. Newton. Railway wheels. (A communication.)
2[illegible]. F. Parker. Carriages.
2651. T. Grason. Boots, shoes, and clogs.
2359. W. and S. Firth and J. Sturgeon. Cutting and boring coal, stone, or other minerals.
2716. J. Macintosh. Taps or cocks.
2760. W. D. Allen. Casting ingots of steel.
2822. L. E. O. Martin. Generating steam.
2827. B. Marriott and C. Radcliff. Watches.
2865. S. Cameron and W. Johnston. Taps or valves.
2874. C. W. Harrison. Filters.
2898. J. Elder. Steam engines.
2901. I. Francis. Washing coal, coke, &c.
2926. H. A. Bonneville. Preserving grain. (A communication.)
2941. J. Steart. Extracting fibre from zostera marina.
2955. J. Lewis. Driving sewing machines.
2958. W. E. Newton. Breaking and cleaning flax. (A communication.)
2967. L. Accarain. Paper, thread, cordage, and fabrics from beetroot.
2970. D. Kirkaldy. Measuring the strength of materials.
2998. M. R. Pilon. Firearms.
3059. H. A. Bonneville. Fret saws. (A communication.)

The full titles of the patents in the above lists can be ascertained by referring back to their numbers in the list of provisional protections previously published.

Opposition can be entered to the granting of a patent to any of the parties in the above list who have given notice of their intention to proceed, within twenty-one days from the date of the *Gazette* in which the notice appears, by leaving at the Commissioners' office particulars in writing of the objection to the application.

LIST OF SEALED PATENTS.

Sealed December 8, 1863.

1348. E. Ironmonger.

Sealed December 11, 1863.

1462. J. Johnson and W. Braithwaite.

Sealed December 12, 1863.

1482. R. Blackburn.
1498. R. W. Gordon.
1505. J. Lightfoot.
1505. J. G. Jennings and M. L. J. Lavater.
1508. J. Steele and W. Mason.
1510. W. Neill.
1511. J. C. Onions.
1512. R. A. Brooman.
1519. F. de Wylde.
1527. D. Barker.
1537. A. Morel.
1538. A. Morel.
1559. W. Clark.
1539. W. Clark.
1582. W. L. and T. Winans.
1584. W. L. and T. Winans.
1585. E. Brooks.
1596. A. E. Brae.
1612. J. Griffiths.
2348. H. Haigh and R. Heaton.

PATENTS ON WHICH THE STAMP DUTY OF £50 HAS BEEN PAID.

3004. B. G. George.
3008. G. Davies.
3027. R. Davison.
3031. W. E. Newton.
3038. J. Townsend and J. Walker.
3039. A. Verwey.
3051. G. S. Harwood.
3054. A. Kyle.
3057. J. Casson.
3071. J. Chubb and E. Hunter.
3079. W. E. Newton.
3084. G. Davies.
3096. E. Barlow, J. Newhouse, and F. Hamilton.
3129. G. Hadfield.
3150. W. Clark.

PATENTS ON WHICH THE STAMP DUTY OF £100 HAS BEEN PAID.

2923. W. and T. Storey.
2940. W. Lund.
2950. J. T. and E. P. Wright.

LIST OF SPECIFICATIONS PUBLISHED.

For the Week ending December 12, 1863.

LONDON, THURSDAY, DECEMBER 24, 1863.

BREAD-MAKING MACHINERY.

ONE of the most important trades carried on in London is the baker's; not because great sums are invested, or great numbers employed, in the production of bread, but because of the relation which the baker bears to every other member of the population, from the highest to the lowest. "Bread is the staff of life," says the old proverb; and it behoves us to see that it does not conceal the sharpness of death, or at least a certain amount of misery, which it is very unpleasant to contemplate. The wholesomeness or unwholesomeness of the chief constituent of our meals, rests in the hands of the baker; to his honesty we must trust for the absence of adulteration, and the good quality of the ingredients employed; and, as we all eat bread, and eat it in quantity, the labours of the baker influence the public health and comfort very materially; more so, perhaps, than those of any other trade. A French physician once attributed a goodly proportion of the crimes committed in the world, to the dyspeptic influences of bad food. Without going quite so far, we may point out that the absence of pure food is generally accompanied by crime. It is not those who are utterly destitute, who run away with our plate, garotte us in the streets, or do murder in our quiet English lanes. There is something essentially demoralizing about filth and bad victuals, and therefore we say that it is by no means unlikely that the baker exerts a more powerful indirect moral influence, than he receives credit for, from any one save the metaphysician.

Most of our readers have heard of Mr. Tremenheere and his labours in the cause of the journeymen bakers of the metropolis—labours set on foot by desire of the Home Secretary, to investigate a statement made by these men, regarding the conditions under which they carried on their labours. Barely eighteen months have elapsed since Mr. Tremenheere's report, with all its sickening details, was laid at the feet of the London world. The little blue book was called disgusting, because the author spoke of things as he found them; the greatest defect which could be urged was, that Mr. Tremenheere was too explicit. It would have been better, perhaps, had he been more so. We cannot well conceive of any occupation more unhealthy than the baker's. The white face, the ghastly look, the short cough, point out the evil influences at work, in a shape not to be overlooked. Dr. Guy states that no class of men, save, perhaps, the Redditch needle-grinders, are liable to so severe and often fatal diseases of the chest. Forty-two years is rather over the usual age when death comes for the prey prepared for him among these men. By that time, late hours, overwork, and an atmosphere so poisoned as to prove deadly to the unseasoned, have done their work; and thus the average life of the men, on whose exertions so much of our comfort, not to say our existence, depends, is far below that of any other trade connected directly with the supply of the more immediate wants of the civilized Englishman.

But if the present system is bad for the operative, what is it for the public at large? We must refer our readers to the blue book for the answer. The details have been often placed before the world. They are far from inviting, and will scarcely bear repetition. The English public is now and then accused of being fastidious. Were it so in the matter of bread, a crusade would have been proclaimed long ago, which would have resulted in the lapidation of the master bakers. John Bull does not so much mind as he ought, the mere aural evidence which may be brought to him of dirt and misery. Unless he see it with his own eyes, he rather refuses to be affected by the testimony of others; and thus our bread continues to be made in such places as these :—"The principal fact which struck me," says Mr. Tremenheere, "was the extreme dirt. In many cases the spaces between the rafters were covered with cobwebs, hanging so closely that a heavy footfall above, must bring large fragments down into the dough beneath. Animals in considerable numbers crawled in and out of the troughs in which the bread was made, and on the walls. The smells from the drains, &c., were very offensive; the draught of the oven continually drawing the effluvia through the bakehouse; and in every case there was a total absence of ventilation. Rats and mice, of course, abounded." This, be it remarked, is not an isolated case. Mr. Tremenheere met with many such. No man can tell whether he is, or is not, supplied from just such an establishment, and in this lies the real secret of the continuance of the system. The public do not believe that the state of affairs is really so bad, and therefore they eat in faith, instead of regarding food so prepared with loathing.

It is a very remarkable fact that an operation so purely mechanical as the mixing and working of dough should continue to be performed by hand. There is no idea more hackneyed than that of performing every conceivable process in the arts by the aid of machinery. It is the absurdity of the day. There are many branches of manufacture in which the most perfect mechanism cannot produce, *for the same money*, the effects of the human hand guided by the brain. There are countless instances wherein machinery cannot at all perform what is required. There is no occasion to cite examples—they are more or less familiar to all. Before, therefore, we join in the insensate cry for those combinations of wheels, levers, and screws, which we are too often pleased to call a machine, let us see whether any process under consideration can really be performed in the best manner by such means; or, granting so much, it is well to examine the problem from a pecuniary aspect, and pronounce judgment accordingly. The mixing of a certain quantity of flour with a certain weight of water, is a process as simple as can be conceived—capable, too, of being performed by extremely simple and well-known mechanical appliances, involving no intricacies of any kind. For this reason, hand labour is one of the worst means which can be applied to the desired end. The practicability of making dough after an improved fashion does not rest on mere assertion. It has been so made both in France and Great Britain for many years. The manufacture of ships' biscuit by machinery has been carried on at Gosport since 1831, when Messrs. Rennie erected the necessary apparatus in order to supply the growing demand for better stores in the Navy. The proper quantities of flour and water are placed in a large circular trough, traversed by a shaft armed with knives or blades, which effectually mix the ingredients by their rotation. Four hundred and fifty pounds of dough are mixed in this way in the space of six minutes. Subsequently, the mass is conveyed to the "breaking-down rollers," as they are termed. These rollers, two in number, about 5 ft. long, and weighing 15 cwts. each, travel backwards and forwards on an iron table or platform, on which the mixed, but unkneaded, dough is placed. These rollers are fitted with spindles at the ends, which revolve in suitable bearings made in the jaws of two forked connecting rods, one for each roller. A large crank shaft at some distance from the kneading table puts the rollers in motion over the dough spread beneath them. The first roller is channelled in a peculiar manner on the surface, so as to break up the smallest lumps; the second is perfectly smooth. Each is fitted with a "doctor" to keep the surface clean. Five minutes suffices to knead 450 lbs. of dough perfectly; the mass being submitted successively to the action of each roller. The sheet of dough is finally cut into hexagonal biscuits by the action of a stamping press. A few minutes' exposure to the heat of an oven serves to complete a process which is perfectly cleanly in its details. Some years since a Mr. Stevens brought out a dough-kneading apparatus somewhat similar in its general construction, which is employed to some extent in the metropolis in making the fermented bread, and regarded with considerable favour.

From the earliest ages, ferments of some kind have been deemed absolutely necessary to the manufacture of true bread, as distinguished from biscuit and its varieties. There is something still to be explained in the peculiar effect which ferments produce on the flour of wheat and rye, the only true bread-making cereals. A certain destructive action is called into play, which results in the formation of a considerable quantity of carbonic acid, to which the light vescicular quality of good bread is due. In addition to this, all the sugar, or nearly all, contained in the wheat, is converted into alcohol, and attempts have been made, ere now, to make the baker's oven perform the part of a still as well; but with very limited success. Spirit of good quality has been produced, it is true; but the nature of the process precludes ventilation, and the bread, as a consequence, acquires a peculiar flavour, too decided to permit it to remain palatable. The loss of the sugar always follows as a result of the use of yeast, and the nutritive qualities of the bread are thereby depreciated. Many attempts have been made from time to time to do away with the use of barm, by the substitution of certain acids and alkalies, whose combination should supply the necessary quantity of carbonic acid gas. The use of such materials is, however, objectionable from various reasons. They all leave neutral salts behind in the bread, which we are better without; and being very subject to adulteration, their use may lead to possibly fatal results without a vast deal of care. The baker's shop is a bad chemical laboratory. Besides, none of these things can do away with that process of manipulation which Mr. Tremenheere has placed before us in such an objectionable light. About three or four years ago, Dr. Dauglish patented a method of making bread by which the use of ferments is totally avoided; the labours of the baker, or rather the bread-maker, reduced to a minimum; and manipulation of any kind entirely got rid of. As a result, the bread produced, is at once clean, pure, and possessed of all its nutritive qualities in the highest degree.

The principle involved, like that in most other good mechanical contrivances, is extremely simple. Taking advantage of the well-known capacity of water for absorbing carbonic acid, whatever its density, in quantities equal to its own bulk, Dr. Dauglish first prepares the water which is to be used

in forming the dough, by placing it within a strong vessel, and forcing carbonic acid gas into it by the aid of a pump put in motion by a small steam engine. The gas is formed by the action of very pure sulphuric acid on chalk, placed within the vessel J, shown in the engraving on another page. The gas is subsequently washed by passing it through water, and ascends into the gasometer A, from which it is pumped, as occassion requires, into either of the vessels marked B, within which it is combined, under a pressure of about 100 lbs. on the square inch, with the water, which absorbs it without any appreciable increase in bulk, and, of course, retains the gas so long as it is kept under pressure, and not one moment longer. The flour, and salt in the form of brine, are conveyed by the shoot C and a tube not shown, into the hemispherical vessel D. As soon as the necessary quantity has been introduced, the valve is closed through which the flour entered. A cock is turned, and a measured quantity of aerated water admitted, or rather forced, by high pressure, into D. A system of knives rotating within, effectually kneads the mass. After a little time a dough tap, as it is called, at E, is opened, and the contents of the vessel expelled in a continuous stream by the pressure within. Here it is that the most remarkable part of the process occurs. The close vessels, the gasometers, the pump, have only been means to this end. As the mass leaves the tap it expands, by virtue of the escape of the gas imprisoned in the water the instant before, into a light frothy dough, which is cut off by an attendant, as shown in the second engraving, weighed, and transmitted to the oven without coming in contact with the human hand for even a second. We have omitted any allusion to minute mechanical details, as it is not necessary to the comprehension of the principle involved, and they only serve to facilitate the operations of the men, without in any way affecting the quality of the product of their labours.

It is impossible to imagine a greater contrast than that which exists between such arrangements as those necessary to Dr. Dauglish's process, and the system of bread-making by hand. The manufacture of aërated bread, as conducted under his patents, is one of the most perfect examples of the adaptation of mechanical means to the attainment of a required end, to be met with in the range of the arts. The great staple of existence reaches the consumer free from contamination, and in the fullest possession of all its good qualities. Were it from no other reasons than these, the application of machinery to bread-making is worthy of serious attention; but when we find that a probability exists that we can thereby materially ameliorate the condition of a hardworking and deserving body of men, Dr. Dauglish's system exerts yet another claim on our good wishes. As to the merely commercial bearing of the question, it would be perhaps premature to speak very decidedly. Hitherto, Dr. Dauglish's patents have been worked on an extended scale only by the London Aerated Bread Company. It is beyond our province to enter into strictly pecuniary details, which are devoid of general interest; we may, however, remark, that the report of the Company, recently published, shows that a profit of 12½ per cent. has been realized during the past year. The result of the declaration of such a dividend has very naturally been the setting on foot of another company, which proposes the introduction of Dr. Dauglish's system of manufacture into every town of England and Wales. The capital required is very moderate, and the n[illegible]mpany will enter into existence under very favourable circumstances, which should command success. Old Father Time perfects many things now and then by a touch of his powerful hand. The manufacture—for so it deserves to be called—of bread by machinery has not yet felt his powers. Four or five years will do much to improve that which is already very good; and we look to Dr. Dauglish's patents, in the hands of a company which possesses skill and energy, as a most important means of bringing within the reach of every man the first necessary of his existence—good and cheap bread.

FOG SIGNALS.

There are only two recognized methods of warning a ship of a dangerous proximity to rock or shoal—one is the lighthouse or beacon; the other, the fog bell or signal gun. Light or sound are the only means of informing a crew of the whereabouts of the otherwise hidden peril; and on their judicious employment depends, in a primary degree, the prosperity of our entire over-sea trade. There is something sacred about the lighthouse and its office, which renders its erection and maintenance a cosmopolitan work. Not one nation alone, but every people on the face of the whole earth, partake more or less of the gracious benefits which its light confers. Hence we find the light-keeper and his duties respected, as a rule, in all civilized warfare. Particular situations, such as the Eddystone rocks, have from time to time, taxed all the energies of the engineer, in his attempt to overcome the difficulties placed in his way by storm and flood. With his success, maritime nations rejoice; with his failure, they mourn. But even the successful establishment of a beacon which shall gleam through the night, is not all that is required. Possibly, the worst enemy the sailor has to contend with in these hard-running latter days, is fog; the all-pervading, insidious, treacherous demon of mist, found everywhere, but making the northern shores of Britain and America his special abiding place. A true fog sets even the electric light, with all its vast powers, at defiance. Thus baffled, sound comes to our aid. The bell and the signal gun have been employed to the required end, from time immemorial, with more or less success. At best, the results obtained are uncertain; and neither bell nor gun can be used with that facility and effect which is so very desirable. Our American friends, long since aware of the objections to which all known means of producing sound hitherto, had been open, inaugurated a novelty, and established a gigantic trumpet blown by compressed air, whose deep thundrous clangor can be heard far out to sea, in spite of the densest fog that ever settled down on the ocean.

It is not easy to find a point of land involving more peril to British steamers and British crews than Cape Race. Wreck after wreck has taken place at or in the immediate neighbourhood of the fatal headland. If fog ever reigns triumphant, it is here. Light fails as a means of warning, and any sound hitherto produced has very imperfectly answered the desired end. A proposal has been made frequently to erect one of Daboll's trumpets, but in vain. The Associated Press of New York offered to provide one; but either from the jealousy of our own Government, or from some other equally powerful cause, that proposition was declined, and the establishment of a fog signal at Cape Race remains under the consideration of our Board of Trade. What the ultimate result will be, we cannot say. Several proposals and schemes have been brought under the notice of the Trinity Board. The only plans which have received much consideration or approval, are those proposed respectively by Mr. T. T. Vernon Smith and Mr. Arthur S. Denny, both of whom have had considerable experience in the construction and working of fog signals—the latter having erected some fifteen in the south-western portion of the United States; and the former, the only one now in operation on British territory. The principles involved in the two inventions are, it appears, pretty nearly the same; and their combination has apparently resulted in the production of a very powerful machine—for we can call it nothing else. The invention is embodied in the use of superheated high-pressure steam, operating upon a combination of colossal steam whistles *tuned in harmony*. The precise nature of the invention, and the views of the inventors, are thus indicated in a little pamphlet recently published by them:—

"It is a theory in the science of acoustics, and experience has proved it to be true in practice, that the power of sound is greatly increased by combination (see 'Essay on Sound,' by Sir J. F. W. Herschell, Bart., F.R.S.), and that harmonious sounds may be heard much farther than discordant ones. This is a feature of the invention. Mechanical appliances of a simple character, and self-operating, regulate or interrupt the sound at certain intervals. Its mechanical arrangements are such, that not only may ordinary signals be conveyed, but messages may be transmitted. Another important feature of it is the manner in which it indicates the particular locality in which it is placed. A certain number of musical airs are familiar to seamen throughout the world. A particular strain may indicate the name of a particular point of land, and may be so described on the mariner's chart. The signal machine may perform this familiar air in the same manner as it sounds the signal, and with the same power. The mariner catching the strain many miles out at sea, and lost in a fog, may, by referring to his chart, know at once, and without any mistake, what point of land he is approaching. The machine requires no attention whatever during its operation, its action being continuous and self-operating so long as steam is kept in the boiler. The construction of it is such, that it can be disarranged only with the greatest difficulty and by design."

To add anything to the mass which has already been written, on the necessity for establishing a fog signal apparatus at Cape Race, would be superfluous. The late accident to the "Africa," speaks for itself in language before which the opinions of the entire press sink into utter insignificance. Yet the mail steamer's mishap, is one of the least of the sad catastrophes which a little money judiciously laid out would have averted. We wish Mr. Smith and Mr. Denny every success in their labours; and from the evidence laid before us, we have little doubt that they have really achieved a mechanical success; and we trust that their invention may win its way into that general adoption which it apparently deserves.

THE ORDNANCE REPORT, 1863, CONDENSED; AND CONCLUSIONS FROM IT.

No. VII.

Value of the Armstrong Gun.

In showing from the Ordnance Report what the Armstrong system is, or rather what it is not—for the evidence proves that, in the construction of the gun, there is nothing of Sir

William's invention but his abortive breech-piece—we incidentally alluded to some of its prominent defects. We did so to illustrate mistakes in the appropriation of other men's ideas and to demonstrate that, in the combinations of the projector, there was no novelty or basis of success, except the contrivances, which resulted in his obtaining an extensive command of the public money.

Resuming the analysis of the Report, we now adduce the opinions of the most important witnesses, as to the value of the system of artillery, which has cost the country so large a sum.

In our last impression, we made it apparent that Sir William Armstrong stood almost alone amongst ordnance constructors, in regarding the coil system, as the most perfect plan of strengthening guns. But, although holding that opinion, he inconsistently admits that, if homogeneous iron or mild steel could be manufactured, in large masses of uniform quality, it would be preferable to coiled hoops of wrought iron. This mode of construction, therefore, is only a temporary expedient; and it is one which other manufacturers of ordnance had either adopted as efficiently as Sir W. Armstrong, or having turned their attention to it, had rejected. These facts are undeniable, and at once dispose of this part of the system, as being of doubtful value. Here is the evidence of the witnesses, beginning with Sir William Armstrong himself. Being asked (No. 4,649): "Then what do you mean by the coil system as applicable to the barrels and the hoops?" He answered: "The gun with the barrel of steel, as exemplified in my first gun." He was next asked, "What is the system of construction, which you say the country has gained?" He replied: "The coil system; but I have made the internal tubes of the gun of both steel and coils; I use the coils as an *alternative* when steel is not to be obtained." He thus actually abandons his claim to the gratitude of the country, by admitting, in contradiction to his former evidence, that steel is preferable to coiled iron. What then is the value of this part of his system, if at any time coiled iron may be superseded by a better material? And what credit is due to him, when it has been proved, that other ordnance manufacturers used coiled iron before and simultaneously with him, as an alternative? Mr. Whitworth says (No. 1,316 and 1,317): "I do not approve of either forged iron or the coil. I have never yet made a gun with a tube of welded iron; I never would think of doing so. I prefer a mild steel or what is called homogeneous iron. Its use for the inner tubes of my gun, I consider a distinctive feature. Sir W. Armstrong, in a letter to the *Times* of November 28, 1861, says: "I was compelled for a time to make the inner tube, *contrary to my principle*, from a solid forging, instead of from coiled iron, and the result has proved the inferiority of the plan." This shows how little reliance is to be placed in Sir William Armstrong's impressions or opinions, proving, what we before stated, that the Ordnance Committee was right in regarding him as a projector of artillery, making ruinous experiments with the public money. Captain Blakely (No. 4,626): "I may say that I consider that the coil system was at that time (1859) a mere makeshift. The object of the coil system is to get welds of wrought iron round the gun, in that form in which they will be least mischievous. But it must be evident that, if we can get rid of the weld altogether, we gain an advantage. Now, ever since 1859, the greatest number of guns that I have made have been made with cast steel where we have no weld." (No. 4,638): "There is no difference whatever between my system and the Armstrong, except that I dislike the coiled iron tube. I prefer to use steel." (No. 4,640): "I think the whole of a moderately-sized gun should be made of steel." Mr. Anderson, the superintendent of the gun factory at Woolwich, an authority which Sir William Armstrong cannot repudiate, says (No. 688 to 692): "I think a solid forging or steel lining is better for the interior of the gun than the coil, though Sir William Armstrong does not agree with me on that point; if we take and forge the iron into solid lumps, and then elongate it into a tube almost 3 in. longer than the bore, and then bore out all the unsound part, the remainder is very sound, and we obtain a very good shell. With the larger guns we pile the great slabs above each other, and then elongate them so that the weld should be distributed through the mass, and so that the weld should be in the line of the gun, and that would tend to make the iron of a uniformly tough kind."

We need not add another word to prove that the boasted coil system is no equivalent for a fraction of the three millions, which it has been the chief means of extracting from the public exchequer. From the great progress already made in producing large masses of iron or steel of excellent and uniform quality, we may conclude, that the days of coiled wrought iron, for the construction of ordnance, are numbered, and that all the Armstrong guns made on that principle will, at no distant period, be thrown aside as unserviceable. There will remain the bitter reflection, that, if justice had been done to Mr. Whitworth, Captain Blakely, the Mersey Company, and others, a great portion of the enormous sums spent on the schemes of the favourite of the War-office, would have been saved, and the country would have obtained rifled guns far more serviceable than those it possesses.

In describing the Armstrong system, in the preceding parts of our summary of the Ordnance Report, we have already furnished abundant evidence to prove that, independently of the want of originality of invention in the parts of the gun, of which the combination is viewed as the Armstrong system, there is no intrinsic value in any one of them. Witnesses, whose testimony must be taken as reliable and conclusive, not only condemn the gun as a whole, but prove the radical defects of the parts separately. As to the coil principle, nobody but Sir William Armstrong adheres to it; and he confesses he does so doubtingly. The breech-loading plan, the vent-piece, the breech screw, the combined polygroove and compression system of rifling, and the lead-coated projectile, are all and each proved to be defective and objectionable, in a greater or a less degree, for the actual service of warfare. Beyond Sir William Armstrong's own evidence, and that of his partners and immediate supporters, there is not a single witness, who does not qualify any favourable opinion he has expressed, by doubts as to the efficient action of some one or other of the parts of the gun, if exposed to rough usage. We have given copious extracts from the Report to that effect. The general tendency of the objections is, that the working appliances of breech-loading and rifling, are much too weak and delicate, and too uncertain in their action, to be relied upon in the field, in batteries, or on board ship.

We might enlarge upon this subject; but the defects of the Armstrong breech-loader are so generally understood and admitted, that we think we have sufficiently fulfilled the task we undertook by proving, on the unquestionable evidence of the Ordnance Report, that that system of artillery is a complete failure. It is evident that Sir William Armstrong himself is of the same opinion. He no longer presents himself before the public as the inventor of the breech-loader. The effects of the 100-pounder, which, in magniloquent strain, used to be termed a 200-pounder, are no longer referred to. Even the *Times* is silent on the merits of this "magnificent" gun, which was, it said, unrivalled. At short range, it is proved to be inferior to the cast-iron 68-pounder in penetrative and battering power. This 100-pounder is repudiated as a naval or siege gun, except for special purposes with other guns, and is utterly condemned for service between decks or in casemated batteries. With those witnesses whose evidence is most in favour of the gun, there is but one voice, in acknowledging that, no matter for what service, the Armstrong breech-loader should be introduced in small proportions with other more serviceable artillery.

This limitation to the use of the gun is its absolute condemnation. It may be tolerated, but it must not be universally adopted; it cannot therefore be regarded as *a service gun*. We defy the most ardent advocates of the Arnstsong system, to show from the Report, that it is applicable for any but exceptional purposes. It therefore has no value as a service gun; it is not the gun the country can rely upon; it is not the gun which justifies the expenditure of three millions to produce it. Consequently, it is not to be wondered at that the Select Committee on Ordnance, with a strong desire, on their part, to deal leniently with the high officials of the War Department, could find no words to exculpate those amongst them, who were compromised by the lamentable contract with the Elswick Company, more decisive than the following: "The Committee is unprepared to impugn the wisdom of the course adopted by General Peel, and followed by succeeding Administrations, with reference to the Elswick Company"—an expression more damaging in character than "damning with faint praise." It tells the Government plainly, "we show you the conclusion we have arrived at, but we abstain from giving it utterance in words."

The 100-pounder—that beautiful piece of highly-finished mechanism, of which a specimen was intended to be one of the glories of the International Exhibition, and a defiance to foreign nations—was held up with pride by its constructor and the War Department, as the perfect type of the Armstrong system. To give it more importance, it was called a 200-pounder. If we take that gun as the standard of the system, we cannot do injustice to from its value. With reference then to that gun, the evidence we have laid before our readers, the following deductions clearly result:—

1. For smashing and penetrating effect at short ranges—those ranges at which siege operations and naval combats are decided—it is inferior to the old 68-pounder smooth-bore.

2. It cannot with safety be used in casemates or between decks.

3. It is weak at the breech end, and the vent-pieces, even with the greatest care, are liable to break and fly out.

4. The soft-coated projectiles are liable to jam in the rifling and render the gun unserviceable.

5. The working parts are so delicate, that a little rust or dirt upon them, will prevent their action.

6. The heavy vent-piece, w[illegible] [illegible]rly

2 cwts., which has to be lifted in and out in loading and unloading, is a serious hindrance to the working of the gun.

7. The 7 in. bore is the extreme limit of the calibre to which the Armstrong system could be applied. Sir William Armstrong virtually made this admission to the Committee; and, in fact, no attempt has been made, to make a larger gun on that plan.

8. Spherical projectiles cannot be fired from the gun.

These are patent facts; their truth and their force, as a complete demolition, of the Armstrong theory, are silently acknowledged by the Government, by the introduction of the Armstrong shunt to replace the Armstrong breech-loader.

The public has been lately entertained by the "graphic" description, in the *Times*, of the performance of the 13 in. Armstrong shunt gun, of which the report has the sensation heading—"Tremendous Smashing Power of the Armstrong 600-pounder."

We shall, on another occasion, show what the Armstrong shunt really is. For our present purpose, it is sufficient to point out, that the very fact of the shunt being brought forward to do the work, for which the original Armstrong gun was intended, is conclusive proof, not only that the latter is an absolute failure, but, that it is abandoned by its astute author, and its once enthusiastic patrons.

But this shunt gun is another incipient Armstrong job. Like the defunct breech-loader, it is heralded into notoriety by exaggerated statements of its power and character. It receives, as all the Armstrong guns have done, the especial attention of the Ordnance officials. It is again the favoured gun. Its defects are glossed over; every allowance is made for the difficulties of a first trial; every opportunity is afforded to remedy and conceal its short-comings. No other great gun meets with the same indulgence and consideration.

To prevent another Armstrong monopoly, into which it is evidently the intention of the Elswick Company to *shunt* the War Department, the public must look to the intervention of Parliament, which happily will soon assemble, and especially to the vigilance of the press, which, in this great national matter, will not fail to do its duty.

We cannot more appropriately terminate this notice of the Parliamentary Ordnance Report, than by giving publicity to the last paragraph of that important document, which is to the following effect: "Your Committee venture to express a hope that the different systems, not of Sir William Armstrong and Mr. Whitworth only, but of the other able men, whose minds are now engaged on ordnance questions, may be fairly experimented upon."

We trust, indeed we feel assured, that the House of Commons will do its duty by requiring the Government to carry out that recommendation of the Committee in a fair and liberal spirit, and by voting an adequate sum of money for that purpose.

SUGAR MACHINERY.*

FEW engineers know anything about sugar machinery, the construction of which has hitherto rested in the hands of a class of machinists who are extremely unwilling to impart the smallest scrap of information. A thorough acquaintance with any particular system of mechanism never comes by intuition; and even the theoretical information which can be gained from the very few books which treat of the manufacture of sugar, is of the most superficial and inaccurate kind. It is sufficiently strange that engineers and sugar bakers—to use an old technical term which no longer retains its literal meaning—should manifest such a peculiar reticence in this matter. Correctly speaking, it is hopeless for an outsider to attempt to gain admission to those mysteries which the guild are determined to keep to themselves, for no good reason that we could ever make out. The silence has been broken at last, the Eleusinian veil torn down, and the mechanical secrets of sugar-refining revealed in all their naked simplicity to the public; and this, too, by a gentleman who has apparently had an extended experience, both home and colonial, in those matters of which he treats. We doubt if a book has been published of late, which will be read with more interest than Mr. Burgh's "Treatise on Sugar Machinery." It is full of defects, both in grammar and style—diffuse where the reader wishes the author had been more concise; and concise to a fault where he might have treated his subject with advantage, at length. Notwithstanding all this, the book is a good book in the fullest sense of the term, because it answers the intended purpose as thoroughly as possible. It forms a complete text-book to what we may term an occult art; and it therefore possesses an exceptional value which cannot fail of appreciation. Details of the actual mode of construction necessary to the erection of a full-sized sugar-mill, are given with minute exactness, the letter-press being illustrated with a set of admirable plates, quite capable of being employed as working drawings. Everything described is of the latest and most improved construction; for the houses engaged in the trade, carry on a keen competition in machinery, which is certain to lead to gradual improvement in matters of detail. Charcoal-burning furnaces, purifying retorts—vacuum pans, all receive a due share of attention, to the smallest particular of nut and bolt, pin or rivet. Mr. Burgh has added rashness to his courage; and not content with risking the wrath and contumely of the "powers that be," whose secrets he throws at the feet of the public, by describing mechanism, he has actually had the hardihood to enter into a minutely detailed statement of prices and estimates, prepared as carefully as though it were actually to be worked from again, as it has probably been worked from before.

The treatise is, in fact, a collection of specifications, describing the method of constructing every portion of a large sugar factory, and stating the price at which the work can be honestly done. The character of the book precludes the possibility of making detached extracts at length; one short one, however, we will give, on the power required to drive a set of crushing rolls, as the question is one which has given rise to many a bitter controversy, and very little is really known about it, even by the initiated, from the absence of accurate experiment.

"The nominal horse-power" (calculated, we presume, as 33,000 lbs. raised 1 ft. per minute), "requisite for a sugar-mill of any given size, taking into consideration all contingent liabilities, will be deduced from the following rules:—The speed of the periphery of the rolls should be about 18 ft. to 21 ft. per minute; the speed of the piston of the engine should be 200 ft. per minute. The motion of the engine being greatly in excess of that of the mill, the latter is reduced by spur gearing in the following manner:—A pinion keyed on the crank shaft works into a large wheel, thus partially reducing the motion; on this wheel shaft a small pinion is also keyed, which works into another large wheel, thereby reducing the motion to the required speed. On this last shaft a sliding clutch is fitted, which connects to the top roll shaft of the mill when required. The surface of the rolls is the chief consideration, as from these the amount of power requisite may be deduced. It is obvious that in practice the surface of rolls of a large diameter has more friction in proportion than that of smaller rolls, for the following reasons:—When two surfaces are in contact, the nearer each is in shape to a straight line, the greater the amount of friction, owing to the surface in contact. Again, when two bodies are in contact, and a third has to pass between them, the less acute the angle of the surfaces from the point of contact, the less friction the three bodies will incur during the movement. The application of a constant number in some cases, would be impracticable. The following rule will be sufficient to enable planters and makers to produce the desiderata, taking into consideration the reduction of speed and friction:—Mills having the surface of their top roll to equal from 20 ft., superficially, require 1-horse power to every two square feet of surface; whereas, rolls with 40 ft. of surface, superficially, require 1-horse power to $1\frac{1}{2}$ square foot of surface, thus enabling intermediate proportions to be obtained."

It is very improbable that the sale of Mr. Burgh's book will be limited to one edition. As it stands at present, it only requires a little revision to render it an important adjunct to the library of the mechanical engineer. This revision, we trust, future editions will receive; and even as it is, we feel no hesitation in recommending the volume to every person who feels any interest in such matters, as the best book on the subject yet published.

* "A Treatise on Sugar Machinery." By N. P. BURGH, Engineer. London: Spon, 1863.

ON THE LOCOMOTIVE ENGINES IN THE INTERNATIONAL EXHIBITION OF 1862.*

BY D. K. CLARK.

(*Continued from page 886.*)

FOREIGN LOCOMOTIVES.—The foreign locomotives exhibited were all made for the English 4 ft. $8\frac{1}{2}$ in. gauge.

The French Department contained examples and designs of various classes of engines, some of them not known in this country. The first is an ordinary passenger engine exhibited and made by the Orleans Railway. It has outside cylinders, with the valves and valve gear outside the cylinders and crank pins. The fire-box is constructed for burning coal, with a long sloping grate, and a transverse water partition or midfeather across the fire-box, above and nearly parallel to the grate, extending backwards from the tube plate and similar in position to the fire-brick arch used in English engines, so as to deflect the flame towards the fire-door and cause it to meet the air admitted there. These are merely varieties of English practice; but the outside gearing is objectionable, for, besides being exposed to accident, the play of the parts arising from wear injuriously affects the working of the valves in regulating the distribution of the steam, to a much greater extent than when the valve gear is inside the wheels. Giffard's injector is applied, the construction being simplified by omitting the mechanism for varying the supply of water. The axles are lubricated from below by means of cotton stumps, which lift the oil by capillary attraction from a reservoir in the bottom of the axle-box.

A six-wheel-coupled goods engine for the Orleans Railway was exhibited and made by Messrs. Cail and Co. It has inside cylinders, with 5 ft. wheels and a wheel base of 11 ft. 4 in. It had already run 13,000 miles on the central division of the railway, where the curves are numerous and sharp and the inclines steep. The fore and hind axle-boxes have

* Read before the Association of Mechanical Engineers.

¼ in. play transversely, and are held taut by springs acting horizontally, which tend to restore them to their central position. The wheels are solid wrought iron, of excellent workmanship, welded at two heats on Arbel's plan. The rim is forged in segments, the nave in two circular halves, and the spokes are let into the rim segments and the two halves of the nave. The whole is clamped together, heated in a furnace, brought out and placed under a large hammer with suitable dies the size of the wheel, and welded on one side. The partially-formed wheel is again heated, and welded complete on the other side. A first-rate piece of work can be done by this process. The counterweights are welded to the rim and spokes of the wheels. The connecting and coupling rods are of cast steel.

The Northern Railway of France exhibited the "Dromadaire" heavy tank engine. The object specially aimed at in this engine was to obtain a considerable supply of steam and great tractive power, in combination with the smallest possible weight. For this purpose the fire-box is placed above the wheels and frame plates, in order to allow of greater width, a larger grate, and more tubes than when at the usual level, without lengthening the boiler. Eleven such engines are at work on the Northern Railway of France, burning coal slack. The roof of the fire-box and its shell are flat and parallel, and stayed together like the sides. The steam space in the barrel is reduced to make room for the tubes, and is supplemented by a tubular steam chamber above the boiler, containing 19 iron tubes, 3⅛ in. outside diameter and ⅛ in. thick, giving 129 square feet of drying surface; through these tubes and also round the steam chamber, the heated gases from the smoke-box pass back to the chimney for drying the steam. The chimney is laid horizontally, in continuation of the annular space which surrounds the steam chamber, since the great elevation of the boiler, nearly 8 ft. from the rails to the centre of the barrel, prevents the chimney being placed vertically with sufficient length.

This heavy-gradient locomotive has eight wheels, 3 ft. 6 in. diameter, all coupled on a base 12 ft. 6 in. long; and two cylinders, 18·9 in. diameter and 18·9 in. stroke. It has 28 square feet of grate, and a total heating surface of 1,667 square feet, having 356 tubes of 1 9-16ths in. diameter. The engine weighs in working order 42½ tons, equally distributed, giving 10 to 11 tons load on each pair of wheels.

A drawing was also exhibited of the passenger tank engines for heavy gradients working on the northern railway of France, in which the ordinary coupling of wheels is dispensed with, and four 14⅛ in. cylinders with 13⅜ in. stroke, and 5 ft. 3 in. wheels on two independent axles are employed. One pair of cylinders and wheels is placed at each end of the engine, with small intermediate carrying wheels 3 ft. 6 in. diameter, on a wheel base of 17 ft. total length.

A second drawing was shown of the four cylinder goods tank engines employed on the same railway, with six pair of wheels 3 ft. 6 in. diameter, coupled in two sets of three, each pair of cylinders working three pairs of coupled wheels: the wheel base is 19 ft. 8 in. long, and the fore and hind axle-boxes have 1¼ in. play, transversely, to admit of running round quick curves of 600 ft. radius. The cylinders are 16½ in. diameter with 17⅛ in. stroke, and the boiler contains 464 tubes 1 9-16ths in. diameter. The weight of the engine is 41 tons empty, and 57 tons full, equally distributed, giving 9 to 10 tons on each pair of wheels.

In the "Dromadaire," and the two other kinds of engine exhibited in drawings by the Northern Railway, the cylinders are outside, and the valve gearing outside them and overhung, which is, as already remarked, the most unfavourable position of gearing for continued accuracy of working. The weight of these engines is top-heavy; and for a run of 230 miles, the length of the line, they cannot well be worked with safety at the occasional high speeds demanded by a large traffic on a long line. The calculations of the capacity of the engines have been based on heating surface as such, which has been assumed to be synonymous with evaporative power. It must be remarked, however, that there is only ·44 in. clear space between the 356 tubes of the "Dromadaire," and only ·56 in. between the 464 tubes of the four-cylinder goods engine: proportions utterly inadequate to maintain an effective circulation and evaporating action on every unit of surface. There can be no doubt that half the number of tubes properly placed would have answered the purpose decidedly better. The best thing about these engines is the uniform distribution of the weight, giving great tractive power without distressing the road on the straight portions; but the wheel base is impracticably long in the four-cylinder engines, and must greatly strain the engine and road, as well as add to the resistance on sharp curves. The proportion of the tractive power, taking the effective mean pressure in the cylinders at 80 per cent. of the boiler pressure for low speeds, is about one-sixth of the weight for adhesion; which is a fair proportion and utilizes the immense weight of the engine.

The designs of an "articulated" tank locomotive of great power, like what is known in England as a bogie engine, were exhibited in the French department by Messrs. Meyer, of Vienna, one of whom is the inventor of the well-known variable expansion gear. On many railways an adhesion weight of 40 tons has now become insufficient, and the necessity for constructing railways cheaply has led to the adoption of steep gradients and quick curves; so that the engines adapted to work these lines must have in certain cases 50, 60, and even 80 tons adhesion weight, with the means of bending or fitting the engine to the curves, since the practice of using assistant engines, or separating the trains into two or more parts in particular situations, is objected to as inconvenient and costly. This engine has a single long boiler of large dimensions, mounted on two separate carriages, with a swivelling connection, each having its own separate pair of cylinders working six coupled wheels placed near together; so that the engine, although of great total length, could readily pass round very sharp curves, whilst the whole of the weight is made available for driving adhesion.

The boiler rests on the front bogie frame by a hollow ball-and-socket pivot at the centre over the middle axle, and on the back bogie frame by two hemispherical bearings on the frame, one on each side of the fire-box. The boiler thus rests on three points, whilst the two bogie frames are each free to follow the curves and irregularities of the road by swivelling under the boiler. The hemispherical bearings at the sides of the fire-box have a limited play, sliding fore and aft to suit the changing position of the boiler relatively to the hind bogie frame. The middle pair of wheels in each bogie have a considerable amount of transverse play allowed them, so as to move laterally in running round sharp curves. The two bogie frames are connected by a single strong coupling rod, having spherical bearings at each end. The whole of the cylinders, valves, and other mechanism is outside the wheels. The steam from the boiler is conveyed to the two pairs of cylinders by connecting pipes with flexible joints, and the exhaust steam from both pairs of cylinders is carried up into the smoke-box by the exhaust pipe through the centre of the hollow bogie pivot, the exhaust from the hind bogie communicating with that of the front by means of a flexible connection.

The distribution of weight on the two bogie frames is such, that the centre of gravity of each of the two portions of the load is at the centre axle. The water tanks are in front, and the coal boxes behind. The total weight of 60 tons is available for adhesion, 10 tons on each axle. Each bogie frame stands on a wheel base of 8 ft. 6 in., and the centres of the two bogies are 22 ft. apart. The wheels are 3 ft. 10 in. diameter, and the cylinders 17¼ in. in diameter, with 19½ in. stroke. The tractive power is estimated at 22,000 lbs., nearly one-sixth of the weight, so as to take a gross weight of 2,360 tons, including the engine, at 10 miles an hour on a level; and 340 tons up an incline of 1 in 40, or 155 tons up 1 in 17, at the same speed.

This plan of locomotive affords, in the writer's opinion, the most satisfactory solution yet given of the problem of obtaining a goods engine of maximum power. With independent bogie frames, each having its own separate pair of steam cylinders, a mass of coupling rods and parallel motions is got rid of, and the resistance of the engine is materially reduced in its working parts and in passing along curves, leaving an important balance of power for useful work.

In the Belgian Department is one 6-wheel coupled inside cylinder goods engine for the Belgian State Railway, made and exhibited by the Société Anonyme de Couillet. The fire-box is a reproduction of the English one previously described in the Chatham and Dover engine, with a long inclined grate, but without the longitudinal water partition. This fire-box affords the same advantage in admitting the hind axle below it, giving a moderate wheel base, in this instance 13 ft. 1 in.; and equalizing the distribution of the weight on the wheels, the loads being as follows:—

Leading wheels	... ...	11·00 tons.
Middle wheels ...	... ...	11·45 „
Trailing wheels	... ...	11·00 „
Total weight	... ...	33·45 „

The connection of the machinery and framing in this engine, is, in the writer's opinion, radically wrong. The three axles each have two outside bearings, carried by two single outside frame plates; and the cranked axle has only one additional bearing 4½ in. long, placed in the centre between the cranks. This single narrow bearing compressed between the two cranks must receive the entire fore and aft strain of the steam pressure; whilst the outside bearings more than 6 ft. apart are 7 in. long, and can receive very little of the fore and aft thrust and pull while the middle bearing is new. But, as the middle bearing must prematurely wear loose, the greater part of this strain will then be thrown upon the outer bearings 6 ft. apart; and this, acting in addition to the strain arising from the loads on the bearings outside, will be likely to break the axle. Again, the fastening of the cylinders to the frame is effected through the valve chests, which are exterior to the cylinders, in two castings spanning the space of 6 ft. between the frame plates: an arrangement which, unless the cylinder castings are made exceedingly strong and heavy, will likewise overstrain and break the connections. On the other hand, by devoting to the valve gear and eccentrics the space on the cranked axle that is usually occupied by the inside bearings, the valve motion is very conveniently accommodated; and probably this slight advantage was the inducement to depart from the usual and indispensable application of inside bearings at the wheels.

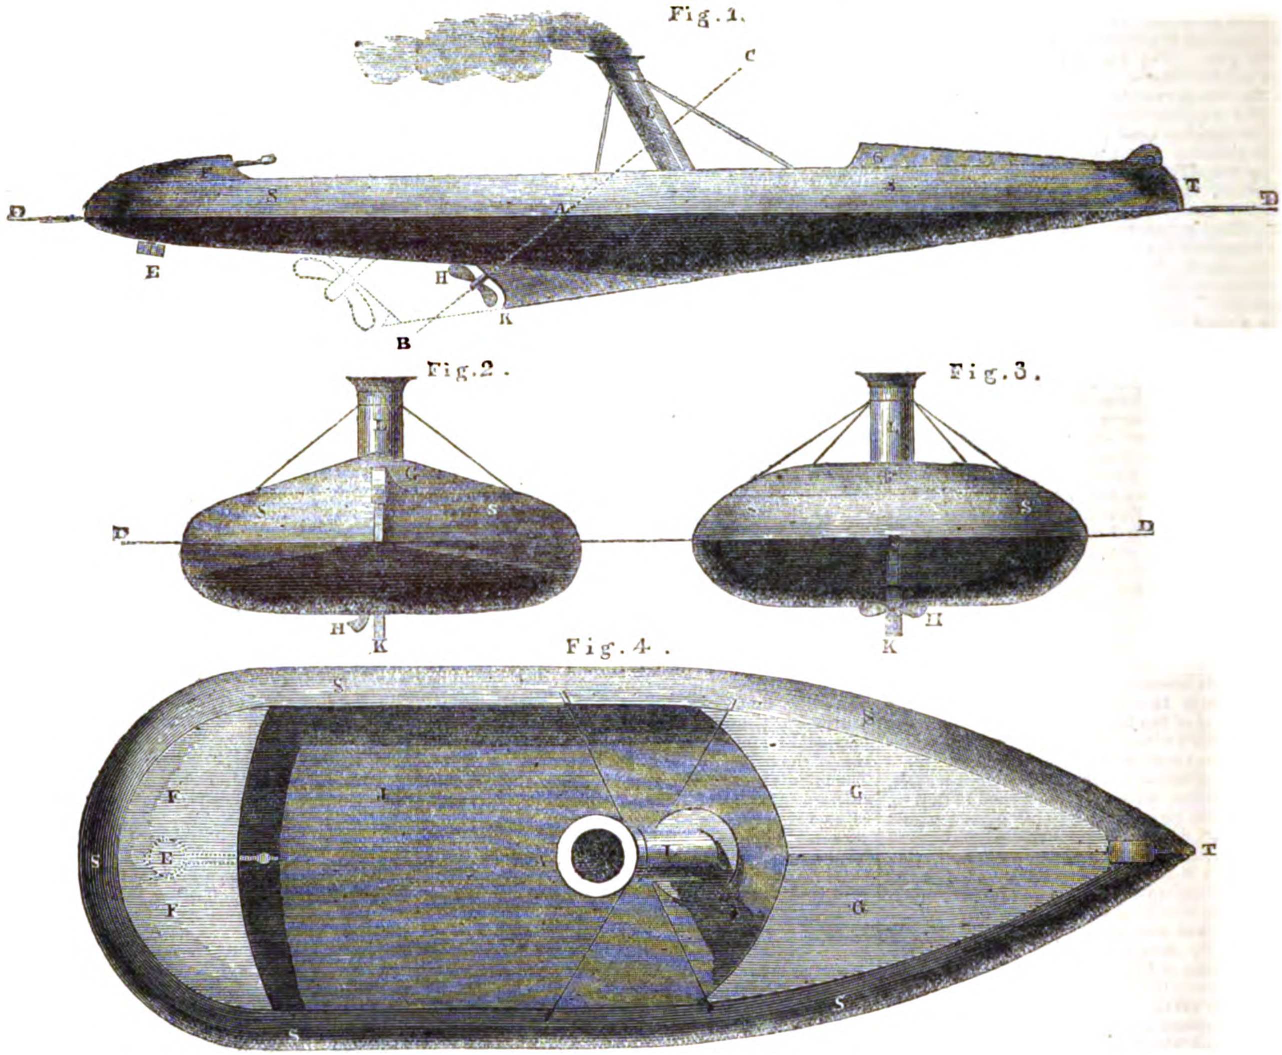
The Austrian State Railway exhibited a passenger express engine, the "Duplex," having four cylinders and four cranks on a single driving axle, specially designed for steady running at high speeds. The usual counterweights in the driving wheels are here superseded, and the reciprocating and working parts are made to balance each other by placing a pair of outside cylinders side by side, and connecting them to a crank and return crank, opposed to each other, on each side of the engine; so that the two pistons on each side and all their connections move in contrary directions and balance each other's inertia. The cylinders are 10½ in. diameter, with 24½ in. stroke, and 6 ft. 9 in. driving wheels.

There can be no question that this system is perfectly successful in effecting the object in view; and had it been brought out twenty years ago, it would, no doubt, have been highly appreciated. But, as the balancing of engines with two cylinders has for the last ten years been completely accomplished for all practical purposes by means of counterweights, the use of four cylinders as in this engine is not likely now to become popular, unless, indeed, railway companies in the race of competition should aim at excessive speeds of 80 or 100 miles an hour.

The Austrian State Railway also exhibited the "Steierdorf," a heavy tank engine with five coupled axles. The boiler rests on two frames coupled together by a pivot bolt. The steam cylinders are fixed on the front frame, and the tank on the hind frame; and the three pairs of wheels of the front frame are coupled to the two pairs of the hind frame by means of an intermediate shaft and radiating parallel motion. This intermediate shaft is ingeniously contrived to adapt itself to the varying angularity of the hind frame on curves, and at the same time to continue to transmit the power from the first to the second frame. The intermediate shaft has overhung cranks on each end, and is carried on spherical bearings by the distance pieces on the front axle of the hind frame; it is also kept at a constant distance from the hind axle of the front frame by the distance links, having spherical bearings at both ends; and the cranks of the intermediate shaft are connected to those of the axles by the coupling rods, all of which have spherical bearings at both ends. The relative positions of the three axles being thus fixed, the power is transmitted from the hind or driving axle of the front frame, through the coupling rods, to the cranks on the intermediate shaft, thence by the coupling rods to the outside cranks on the front axle of the hind frame, and further by coupling rods to the hindmost axle. The wheels are 3 ft. 3½ in. diameter, the cylinders 18½ in. diameter with 24⅞ in. stroke, and the total weight in working order is 46 tons. The fire-box, made for burning coke, has 15 square feet of grate; and the boiler contains 158 tubes 2 1-16th in. diameter, with ·69 in. clear space between them.

In the Prussian Department one engine was exhibited by Mr. A. Borsig, of Berlin. It was a six-wheel four-coupled engine, with outside cylind[illegible] 7 in. diameter by 22 in. stroke, and driving whe[illegible] of 4 ft. 6 in. diameter, the hind wheels being coup[illegible]

GILES'S OCEAN BLOCKADE RUNNER



and all the axles being between the fire-box and smoke-box. This type of engine is exclusively employed on the Minden and Cologne Railway for mixed and goods trains; and also on many other German railways. The free use of steel in the construction of this engine confers on it an air of lightness, perhaps too great lightness, which contrasts strongly with the heaviness of the tender.

The proportions of the boiler are good; and this circumstance, in addition the very excellent and well finished work, may account for the popularity of that class of engine; but it has some grave defects, which must detract from its usefulness. The suspended weight is carried on three points, by a cross spring over the leading axle and compensating or equalizing levers connecting the springs of the two driving axles on each side of the engine. This notion of a triangular elastic bearing with the apex in front, much thought of at one time, is now nearly discarded in England, on account of its giving the engine a dangerous freedom of movement at high speeds.

The cylinders are fitted with double valves for variable expansion, the expansion valve being on the back of the other, with a central passage for steam through it: the lower or leading valve is worked by a link motion in the usual manner; and the upper valve by a separate rod from the fore eccentric working in a grooved sector, from which a variable travel and cut-off are communicated to the valve. The steam port opens for the exhaust at 90 per cent. of the stroke for all degrees of expansion, and is only opened ⅜ in. for the exhaust when the piston arrives at the end of the stroke; and as the steam ports are very small in area, each being only 1-20th the area of the piston, there can be no doubt the back pressure is very considerable in consequence, and more particularly with an outside cooling cylinder. For a 17¼ in. outside cylinder in the Caledonian engine previously described the area of steam port provided is 1-11th that of the piston, whilst the valve is open full port for the exhaust when the piston reaches the end of the stroke. Moreover, it is not good practice to keep the same point of the stroke for the exhaust under all degrees of expansion; high expansive working usually accompanies high speeds, and therefore the exhaust should be made to open earlier in the course of the stroke for the higher grades of cut-off, in order to give the steam greater liberty for escape before the piston returns upon it. These conditions of the good working of steam are comprehended in Stephenson's expansion link motion, and are now thoroughly appreciated and established in English practice; and the other attempts at expansive valve motion for locomotives have been abandoned in this country.

In employing steel for the working parts of this engine, such as the piston rods, the connecting and coupling rods, and the crank pins, the dimensions of the wearing surfaces have in some cases been reduced. The bearings of the coupling rods are reduced in proportion to the size of the rods; though it is reasonable that as the strains remain the same the sizes of the wearing surfaces should not be altered. The axle-boxes are of wrought iron.

In the Saxon Department a six-wheel four-coupled engine was exhibited by Mr. R. Hartmann of Chemnitz, specially designed to work in mountainous districts. It is, in fact, a bogie engine, having four coupled wheels 4 ft. 6 in. diameter with 21 tons on them for adhesion, and a swivelling truck on Bissell's plan in front with 7 tons load, making a total of 28 tons. The cylinders are 15 in. diameter by 22 in. stroke; and are outside, with outside valve gearing, as is so prevalent a custom on the Continent. The framing has two longitudinal plates 8 in. deep and 1⅜ in. thick, to which the cylinders are fixed, with 16 in. of overhang. This is an excessive overhang upon so narrow a frame plate, and the valve gear being still further overhung the valve hops about at every stroke as the axle-boxes wear. Overhung eccentrics for valve gear outside the crank pin never do well for heavy work in consequence of the unsteadiness. The best feature in this engine is the swivelling truck with a triangular frame, which carries the fore part of the engine on one pair of wheels with a limited but sufficient allowance of lateral play, and radiates on a pivot behind it fixed under the boiler. With a flexible wheel base only 11 ft. 9 in. long there is no doubt that in this engine and in others of ordinary size the Bissell truck is well adapted for leading round the quickest curves likely to be found in practice.

In the Italian Department an inside cylinder six-wheel-coupled locomotive is exhibited from the Pietrarsa Royal works, Naples, which is a creditable specimen of the old school of locomotive.

AN OCEAN BLOCKADE RUNNER.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

SIR,—Will you permit me to call the attention of the public to the advantages of a novel steam ship of my invention, through the medium of your valuable paper.

The ocean offers advantages for the attainment of a high rate of speed in locomotion superior even to the land; one of the foremost of which is its greater safety, there is no fear of getting off the rails; and the area of locomotion not being so limited or so intricate, the chances of collision, under

judicious management, are less. The requirements of society in their social as well as political aspect, now also need a more active and energetic system of intercommercial and international communication, for the purpose not only of securing an efficient distribution of the necessities and conveniences of life, but also to counteract within healthy limits the ever too great tendency of governmental interests to impede the channels of traffic and trade. We now see large territories possessing plentiful supplies of those commodities which the manufacturing interests of Europe stand particularly in need of, blockaded by either French, American, or English war vessels; and from the fact that European Governments are now in possession of all the fruits of past mechanical invention and enterprise, and are rapidly constructing everywhere large fleets of vessels especially intended for war (which means for the destruction, suppression, or controlling of commercial enterprise), it is all the more necessary that the productive and progressive interests of society should investigate still further the principles of mechanical science, and provide themselves with agencies for evading or counteracting a too complete control of their operations. As civilization has extended its influence over new territories and widened the area of its settlement, it has been accompanied by a corresponding development in mechanical science. America (at the period of its settlement considered a distant country) has by the aid of steam power and other mechanical appliances been brought into close relationship, both socially and commercially, with Europe. This mechanical system has also, under the influence of industrial and commercial enterprise, effected settlements in the distant territories of the southern hemisphere, and the first links of social and commercial sympathy between Europe and Australia, Japan and China, have been already constructed. To contribute to the growth and maturity of these relationships, it is necessary to solidify the interests of commerce and trade by more energetic, constant, and rapid communication, and then these vast territories will present multiplied repetitions of that commercial development and social progress which has existed hitherto almost exclusively with the American continent.

The discovery of the principle of *traction by gravity* or *oblique propulsion*, which is an expression of the mechanical power employed so as to bring into horizontal co-operation the latent force of *gravity*, opens up a great advance in efficient and economical effect both in land and water propulsion, and offers to the mechanical and commercial interests of the world, the means for accomplishing an immense stride, both in stimulating the development of their agricultural resources, and the more active and economical distribution of merchandise exclusively by steam power. This mechanical principle, which is the same as that employed in the construction of "Giles' Bull," is illustrated in its application to water propulsion in the engravings on the preceding page.

In water propulsion there are two chief points to be considered—the one is *resistance to the vessel*, the other *resistance to the screw*. The first, or resistance to progress, should be as small as possible; the second, or resistance to propulsion, as great as possible. The mechanical properties of water offer very great facilities in the construction of the vessel for effecting these ends, because, although water is not an elastic liquid, and therefore does not increase in density by depth, yet depth increases its solidity, and at 30 ft. below surface, it needs fourteen times the power to displace a given area than at the surface. The mechanical properties of water are like that of a pile of bricks; there is the same density of substance in a brick taken from the top as from the bottom of the pile, but the upper tier could be removed by a force which would make no impression on the lower tier. The obstacles hitherto to the efficiency of the screw have been want of immersion, and when that has been attained, the increased resistance to the vessel's progress in consequence of her increased draught of water. The two chief conditions of rapid ocean traffic are therefore *lightness of draught for the vessel*, and *depth of immersion for the screw*. Both these objects are attained by the above mode of construction; and in addition to the fact that there is no sacrifice of propelling power from its oblique application, because another (otherwise latent) force, *gravity*, is brought into horizontal co-operation (*without friction*); so also there is a great mechanical economy effected by expressing the propelling force downward, it being across the current made by the vessel's progress. By this method, vessels of light displacement can be fitted with screws of almost any power, by extending the keel aft, according to the dotted lines in fig 1, and prolonging at the same time the stern of the vessel, so as to bring the centre of gravity over the screw. The vessel tapering off at each extremity, and having no keel except amidships, secures also the easiest possible steering, and the most ready reply to the least motion of *the helm*.

Fig. 1 represents the side view; fig. 2, the bow; fig. 3, the stern; fig. 4, the deck. The keel starts out from the bilge or deepest part of the vessel extending aft and downward in a line from the bow, and the screw shaft is placed at an angle of, say, 30 to 40 deg. with the horizon, the thrust of the shaft being taken at or near the vessel's centre of gravity, A. A speed of 30 to 40 miles per hour, in fair weather, is attainable by this method.

The best guarantee for the interests of commerce against any abuse of power by the vast fleets of ironsided coffins now being constructed by the Governments of Europe, is *a light pair of heels*.

JOHN GILES.

London, December, 1863.

THE WATER MILLS OF ARGOSTOLI.

A CURIOUS natural phenomenon occurs, and is taken advantage of, in the neighbourhood of Argostoli. At four points on the coast, the sea, at its ordinary level, enters a very narrow creek, or broken rocky channel, and after running somewhat rapidly through this channel and among broken fragments of rock for a short distance, it gradually becomes sucked into the earth and disappears. By conducting the water through an artificial canal for a few yards, and so regulating its course and forcing all the water that enters to pass in a single stream beneath an undershot wheel, power enough is obtained in two cases to drive a mill. Mills have, in fact, been placed there by an enterprising Englishman, and are constantly at work. The stream after being utilized, is allowed to take to its natural channel, and is lost among the rocks.

It is common enough to drive a wheel by a current of water going from the land towards the sea; but it is certainly rare, and, as far as I am aware, peculiar to the locality, to find mills driven by a current of sea water, acting quite independently of tide, the water constantly and steadily rushing in over the earth's surface and finally disappearing. It is not the river god pursuing the nymph, but the great Neptune himself invading the domain. No wonder the Cephalonians are proud of their mystery; and it will be interesting to consider the circumstances attending it.

Apart from the facts that the water sucked into the earth is sea water, and that it enters below the sea level, there is nothing extraordinary or unusual; for numerous instances occur in every limestone country of streams, often of very considerable dimensions, entering into open fissures and disappearing. In England there are two or three cases of this kind; and in the Ionian Islands absorption of water into the earth is so rapid, that there is hardly an instance of any appreciable quantity of the rain-fall being retained long enough on the surface to form streams and carry off the water to the sea. Almost all the rain is there absorbed, and this is certainly the result of the cracked and broken nature of the limestone rock—of the numerous natural caverns penetrating every part—of the constant enlargement of fissures into caverns in one place, and the choking up of caverns by stalagmite and stalactite in another—and of the especially fissured and cavernous nature of certain kinds of limestone, of which the rocks found in the Ionian Islands and Greece afford notable examples.

But it is certainly very seldom that we are able to satisfy ourselves of the empty state of the limestone caverns close to the sea and below the sea level, as we can at Argostoli; and for this reason, if for no other, the phenomena are worthy of particular notice.

The general condition of the surface is as follows:—The small harbour of Argostoli is enclosed on both sides by the hard, broken, limestone rock so common in the islands. On the east side it rises immediately into hills of moderate elevation; and on the west side, behind the town, there is a plateau, scarcely above the usual level of the water, rising about two or three hundred yards from the shore into a low ridge, which, in fact, by its projection into the gulf makes the harbour. Between the shore line and this low ridge there is an evident depression of the surface in all that part over which the sea when it enters is sucked in. There is evidently beneath this part an extensive cavernous tract, which may well hold much more water than during any ordinary season or succession of seasons can drain naturally into it in consequence of the rainfall at the surface.

But what, it will be asked, becomes of the waters of the sea thus pouring in continually to fill the cavern? Certainly, in time, any cavity must be filled, if it has no natural outlet, and if water is constantly entering it. How, also can the water run off, if its level in the cavern is below the sea level? It is not, perhaps, so difficult as may be thought to answer these queries.

The water that everywhere enters the earth is always circulating. It not only pours down into and amongst all rocks, but is afterwards lifted, and the level of these subterraneous stores is greatly elevated by operations going on at the surface, often at a great distance above.

The cause of this is evaporation, which proceeds incessantly from the surface of all rocks, but especially from limestones. The narrow crevices, common in limestone rocks, act as capillary tubes. When water falls on the surface of such rock, it finds its way down readily, and this seems quite natural; but when, in hot countries, where there is a long summer season of great drought, the surface becomes dry and hot, moisture rises in steam from below; and, as the heat and dryness increase, the accumulated waters become more and more exhausted. All this goes on without reference to the actual level of the water line within the earth, which may be far beneath the level of the sea.

That this is the case in the softer limestone rocks, even when not cracked, has been proved by actual experiment. That it takes place to an enormous extent in the limestones of the eastern Mediterranean is proved, if in no other way, by the fact that vines, planted among bare stones, without soil, obtain an ample supply of moisture from the earth, and ripen their fruit to perfection in the hottest and driest seasons. No doubt the earth and rocks are hot, and appear dry; but so long as there remains any water below that has passed down during the rainy season, so long will a part of that water be given back to the dry and thirsty soil above.

If then, as is probably the case, there is so large an evaporation from the part of the surface of the Island of Cephalonia, within range of this district, as to keep the water level of the year below the sea level, in spite of the joint supply of rain and sea water, it is clear that the water may run in for ever at the same rate without filling up the space. And this I believe to be the correct explanation of the phenomenon.

The influx of water, however, is not small. It amounts, as far as I could make out, to more than half-a-million of gallons per diem, for the two mills together. The fall of water from the sea level into the cavities, where it disappears, seems to be little more than a foot or eighteen inches.

There appears to be something like a lunar tide in the harbour and gulf of Argostoli, the water entering and flowing out twice a day, and the level of the water varying about 6 in. in ordinary weather, and when there are no disturbing influences. Any wind blowing steadily for some time, and all storms, whether at a moderate distance or near, affect the water level in a marked degree, and complicate the apparent tide. In one of the cavities where the water disappears from the surface, the level of the surface of the water below may always be reached, and it is said to rise and fall with that of the sea, even when the influx of the water is stopped. This is quite possible, without assuming a free communication, which would of course at once fill the cavern to the sea level.

There is a constant tendency to choke up the crevices through which the water disappears, by a seaweed very common on this coast. This and the silt would probably soon interfere greatly with the current that enters the crevices, if the channel were not kept artificially clear. The water, however, is greedily and rapidly absorbed by the whole surface of broken ground near the sea, between the two mills.

It will be evident that if the sea water finds its way into any large natural cavity from which it is afterwards evaporated, a deposit of salt must be taking place in this cavity, or in rocks adjacent or connected with it. Assuming the influx to be at the rate already mentioned, this may be estimated roughly at about equivalent to an area of 10 acres or 12 acres of solid matter, 1 ft. thick, accumulated each year. It is an interesting question to consider where this deposit is going on, and whether saline springs may not thus be fed. Th[illegible] no known

springs in the Island of Cephalonia that present any large quantity of saline matter.

Note.—Not having the means of accurate measurement, and not being able to learn that the quantity of water entering the land has ever even been estimated by the mill owners, I can only give these quantities as rough approximations to the truth.—*Ansted's "Ionian Islands in* 1863."

INSTITUTION OF CIVIL ENGINEERS.

THE annual general meeting of the Institution of Civil Engineers was held on Tuesday, December 15—John Hawkshaw, Esq., President, in the chair.

The report stated, that in the interval that had elapsed since the last annual general meeting, it was gratifying to the Council to be able to state that the progress of the Institution had been eminently satisfactory. The Papers read at the meetings had been numerous and varied; the meetings themselves had been very fully attended; the library had received considerable accessions, both by donations and purchases; the number of members had steadily increased; and the funds were in a prosperous condition. These were certain tests that the Institution continued to be appreciated by those in whose interest it was established, and led to the conclusion that, so long as its affairs were conducted as they hitherto had been, similar support and countenance would be extended to it. An enumeration of the Papers read and discussed at the ordinary general meetings showed the variety of subjects which engaged the attention of engineers at the present day, and the extended area embraced within the operations of the members of the profession. Many of the Papers read during the last two Sessions had, at the request of the authors, been issued already in a separate form, so that the volumes xxi. and xxii. of the Minutes of Proceedings, for the Sessions 1861-62 and 1862-63 might be said to be completed, and would be issued in the course of a few weeks. An index of the series from vol. i. to vol. xx. inclusive was in hand, and though a task involving considerable labour, had already advanced fully one half. Numerous applications having been received from the members for complete sets of the Minutes of Proceedings, the Council had determined to reprint some of the earlier numbers which were out of print, in order to be enabled to supply this evident want. The tabular statement of the transfers, elections, deceases, and resignations, showed that the number of elections had been 74, of deceases 26, of resignations 5, and of erasures 3, leaving an effective increase of 40, and making the total number of members of all classes on the books on the 30th of November last 1,040. This was an increase of nearly 39 per cent. in the last ten years, of which 4 per cent. occurred in the past session. During the last ten years the number of Members had increased to a greater extent than the Associates; for, whereas the numbers of those classes on the 30th of November, 1853, were 259 and 441 respectively, or in the proportion of 1 to 1·7, on the 30th of November last these numbers were 425 and 588, or as 1 to 1·4.

The deceases during the past year had been:—John Singleton Copley (Lord Lyndhurst) and William Tooke, Honorary Members; Thomas Evans Blackwell, William Clegram, Richard Carden Despard, James Fenton, Joshua Field, Joseph Glynn, Mark Jones, William Lewin, and Captain William Scarth Moorsom, Members; Beriah Botfield, M.P., Alexander Bremner, Alexander Brodie Cochrane, William Coulthard, William Cubitt, M.P., William Dunlop, Charles Michael Jopling, Francis Morton, Geddie Pearse, Apsley Pellatt, William Rigby, Charles William Scott, James Sherriffs, Admiral Washington, and William Richard Whitmore, Associates. It would be observed, with deep regret, that while the Institution had lost many useful and able members, there was included in the list one whose memory must ever be regarded with the liveliest interest; for to Mr. Joshua Field, to whom allusion was made, was due, in no small degree, the existence of the Institution of Civil Engineers. It was about the year 1816 that Mr. Henry Robinson Palmer, who was then articled to Mr. Bryan Donkin, first suggested to Mr. Field the idea of forming a society of young engineers, for their mutual improvement in mechanical and engineering science; and it was no doubt owing to Mr. Field's influence that Mr. William Nicholson Maudslay became the third who associated in this cause. These were shortly joined by five others—Mr. James Jones, Mr. Charles Collinge, Mr. James Ashwell, Mr. Thomas Maudslay, and Mr. John T. Lethbridge; and when the Institution was constituted on the 2nd of January, 1818, it comprised just these eight members, and so remained until the following year, when the num-

NEW SPECTROSCOPE.

FIG. 1.

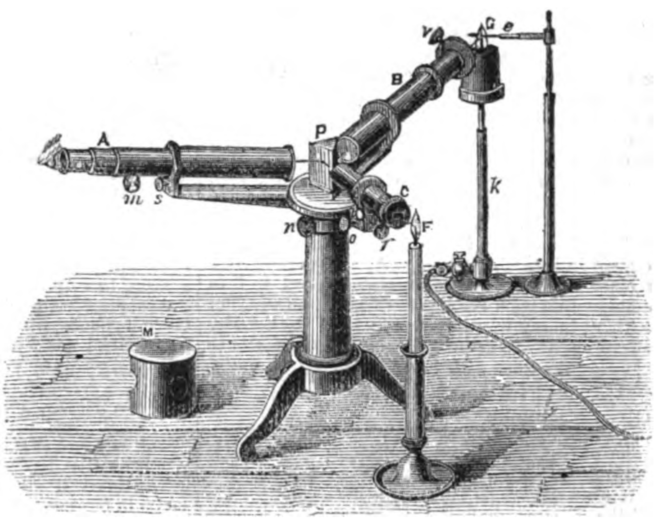

FIG. 2.

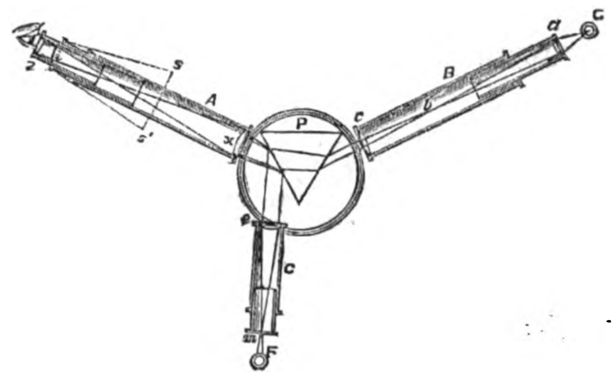

ber was increased by three. From that time to the present the numbers had steadily increased, the first great impetus being the acceptance of the office of President, in 1820, by Telford, under whose fostering hand the Institution grew rapidly in importance, and eventually acquired a permanent position among the scientific societies of the metropolis.

The abstract of receipts and expenditure, as prepared by the auditors, showed that the income from all sources, during the twelve months from the 1st December, 1862, to the 30th November, 1863, was £3,974 17s. 1d., while the payments in the same period only amounted to £2,740 8s. 11d., leaving a balance of £1,234 8s. 2d. Of this, a sum of £1,000 had been invested in the purchase of London and North-Western Railway Four per Cent. Debenture Stock, making a total of investments during the last five years out of the general funds of £3,500. The realised property of the Institution now comprised:—1, General Funds, £9,357 0s. 8d.; 2, Building Fund, £1,322 2s. 11d.; and 3, Trust Fund, £9,970 12s. 7d., making a total of £20,649 16s. 2d., as against £19,041 12s. 1d., at the same period last year.

After the reading of the report, Telford Medals and Telford Premiums of Books were presented to Messrs. J. Brunton, J. R. Mosse, Z. Colburn, and H. Hayter; Telford Premiums of Books, to Messrs. W. M. Peniston, W. H. Preece, A. W. Makinson, D. Miller, R. Crawford, W. Cudworth, and J. G. Fraser; and a Watt Medal and the Manby Premium, in Books, to Mr. J. Fernie.

The thanks of the Institution were unanimously voted to the President, for his attention to the duties of his office; to the Vice-Presidents and other Members and Associates of Council, for their co-operation with the President, and their constant attendance at the meetings; to Mr. Charles Manby, Honorary Secretary, and to Mr. James Forrest, Secretary, for the manner in which they had performed the duties of their offices; as also to the Auditors of the Accounts and to the Scrutineers of the Ballot, for their services.

The following gentlemen were elected to fill the several offices on the Council for the ensuing year:—John R. M'Clean, President; J. Fowler, C. H. Gregory, T. Hawksley, and J. S. Russell, Vice-Presidents; Sir William Armstrong, W. H. Barlow, N. Beardmore, J. Cubitt, T. E. Harrison, G. W. Hemans, J. Murray, G. R. Stephenson, C. Vignoles, and J. Whitworth, Members; and Colonel Jervois, C.B., R.E., and Mr. C. Waring, Associates.

The meeting was then adjourned until Tuesday, January 12, 1864, when the Monthly Ballot for Members would take place, and the following Paper would be read:—"On the Closing of Reclamation Banks," by Mr. J. M. Heppel, M. Inst. C.E.

NEW SPECTROSCOPE.

A MODIFICATION of the spectroscope has been recently introduced in Paris, and already attracts a great deal of attention in the scientific world. We are indebted to our able contemporary, *Les Mondes*, for the accompanying engravings of this instrument. It consists of three small tubes fitted with lenses, mounted on a single pedestal or stand, common to them all, and converging towards the faces of a flint prism, as shown in fig. 1. The telescope A can be moved at pleasure round the prism, the clamping screw *n* serving to fix it in any given position. The milled-headed screw *m* serves to adjust the focus, and that marked *s* the angle of inclination of the instrument.

In order to understand the uses of the tubes B, C, we must refer to fig. 2, which represents the changes in direction undergone by the rays of light which pass through the apparatus. The rays emitted by the flame G pass through the lens *a*, which causes them to converge at the point *b*, the focus of a second lens *c*; consequently, a pencil of parallel rays quit the telescope B and enter the prism P, where the light is decomposed, the bands of colour being rendered visible by the lens *x* and the eye glass *s*, which give apparently at *s*, *s*, a correct picture of the spectrum magnified eight times lineally.

The instrument C serves to measure the relative distances of the lines of the spectrum.

In order to do this, its anterior extremity is fitted with a peculiar glass scale, micrometrically divided into 250 equal parts. In order to prepare this scale, a paper riband is provided in the first instance, on which is carefully engraved a scale 250 millimetres long, graduated by tens. From this a negative copy is taken on glass, reduced in length, from 250 to 15 millimetres. The black lines on the original paper riband are reproduced in white on the glass scale, which is adjusted in the extremity of the tube C exactly in the focus of the lens c. This lens projects a pencil of parallel rays on the central prism, proceeding from the flame of a lamp or candle at F. These rays being subsequently reflected from the inclined face of the flint, are conveyed into the telescope A, where they give a clear image of the glass slide placed in C in combination with the image of the spectrum, but without in any way interfering with it, thereby affording a means of measuring the distance between the lines with great precision.

THE TENDERS FOR THE THAMES EMBANKMENT.

THE Metropolitan Board of Works received the following tenders on Friday, for the second portion of the Thames Embankment—namely, that part from Waterloo-bridge to the eastern end of the Inner Temple. The tenders were fourteen in number, as follows:—Mr. George Furness, £241,500; Mr. Thomas Pearson, £264,000; Messrs. Hickersley and Baylis, £257,000; W. Webster and Co., £240,000; Messrs. A. W. Ritson and Co., £229,000; Mr. T. Dockra, £260,000; Mr. J. Diggle, £229,400; Messrs. Rogers, Doon, and Co., £238,500; Mr. W. Dettrick, £232,353; Mr. W. Tatam, £264,000; Messrs. W. M'Cormack and Co., £240,656; Messrs. T. Brassey and Co., £238,500; W. Moxon and Co., £243,195; and Mr. W. Lavers, £239,800.

The Board resolved itself into a committee to consider the tenders, and when the sitting was resumed, a report was brought up by Mr. D'Iffanger, recommending that the tender of Mr. Ritson should be accepted, subject to the usual inquiries. This was seconded by Mr. Legge, and carried *nem. con.*

TO CORRESPONDENTS.

The MECHANICS' MAGAZINE is sent post-free to subscribers of £1 1s. 8d. yearly, or 10s. 10d. half-yearly, payable in advance. Post-office orders made payable to Mr R. A. Brooman, of 166, Fleet-street, E.C.

Advertisements are inserted in the MECHANICS' MAGAZINE at the rate of 6d. per line, or 5½d. per line for 6 insertions, 5d. per line for 13 insertions, 4½d. for 26 insertions, and 4d. a line for 52 insertions. Each line consists of about 10 words. Woodcuts are charged at the same rate as type. Special arrangements made for large advertisements.

All communications should be addressed to the EDITOR, 166, Fleet-street.

To insure insertion in the following number, advertisements should reach the office not later than 5 o'clock on Thursday evening.

AARON SMITH.—The invention you speak of is, we believe, the subject of a French patent. What the mode of manipulation on which the success of the process apparently depends may be, we cannot inform you. Hoofs may be dissolved by long boiling in water, slightly acidulated with muriatic acid, or in a Papin's digester, or in dilute muriatic acid.

PRESSURE.—Why not? Dr. Alban once worked an engine with steam of a pressure of 1,000 lbs. per square inch in London.

TRACTION (Woking).—The pitch chain is incomparably the best. It is very difficult to employ springs and gearing in combination.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

SIR,—I shall feel much obliged if you, or any of your correspondents, can give me in your next journal answers to the following questions, viz.:—

(1.) What is the thickness of metal of an 11 in. Dahlgren gun at the breech, trunnions, muzzle, and behind the bore?

(2.) What length of bore of an 8 in. gun does a 16 lbs. charge occupy?

(3.) How many degrees of elevation, depression, and lateral range can be given to a 68-pounder when used at the port holes of the "Warrior"?

I am, your obedient servant,

A. F.

Glasgow, Dec. 21, 1863.

Correspondence.

STRENGTH OF METAL, BEAMS, GIRDERS, AND BOILERS.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

SIR,—In my letter under the heading "Stress upon Boilers and Boiler Plates," published in the MECHANICS' MAGAZINE November 20, 1863, it is stated in the last paragraph of that letter, p. 808, that, "in mixing metals, if the tension *plus* the compression of the metal, both within the elastic limits, be a given quantity, that metal will be the strongest possible in which the strength in tension is equal to the strength in compression, the neutral axis being in that case at the middle of the depth which," it is there stated, "is the best position of the neutral axis, if the metal, as in the weight upon a beam, be subject to one strain only."

As the subject is of considerable practical importance, I submit, with your permission, the following demonstration of the proposition:—

Let b = breadth, D = depth, of a rectangular metal beam or joist.

t = tension, c = compression of the metal, both within the elastic limits.

d' = depth of the metal in tension.

D — d' = depth of the metal in compression.

The tension, multiplied by the depth of the metal in tension, = the compression, multiplied by the depth of the metal in compression;

$$\text{or, } t\,d' = c\,(D - d') \qquad (1)$$

$$\text{hence, } d' = \frac{c\,D}{t + c} \qquad (2)$$

In rectangular beams, $l = 1$.

$$\text{Strength} = \tfrac{1}{3}\,b\,D\,t\,d' = \frac{\tfrac{1}{3}\,b\,D^2\,t\,c}{t + c} \qquad (3)$$

By the Proposition we have,

$$t + c = \text{a given quantity} = a \qquad (4)$$

$$\frac{\tfrac{1}{3}\,b\,D^2\,t\,c}{t + c} = \text{a maximum.}$$

Differentiating with respect to t and c,

From (4), $d\,t + d\,c = 0$

$$\text{,, (5), } \frac{\tfrac{1}{3}\,b\,D^2}{(t + c)^2}\left\{(tdc + cdt)(t + c) - (dt + dc)\,tc\right\} = 0$$

Dividing, and substituting — dt for dc, we have,

$$-t^2dt + ct\,dt - ct\,dt + c^2dt - ct\,dt + ct\,dt = 0 \ldots (5)$$

$$\text{hence } -t^2dt + c^2dt = 0$$

$$\text{and } \quad t = c \qquad (6)$$

EXAMPLE.

1.—$b = 4''$; $D = 12''$; $t = c = 1$; $t + c = 2$.

$$\text{By (2), } d' = \frac{c\,D}{t + c} = \frac{1 \times 12}{2} = 6.$$

$$\text{,, (3), Strength} = \tfrac{1}{3}\,b\,D\,t\,d' = \tfrac{1}{3} \times 4 \times 12 \times 1 \times 6 = 96.$$

2.—$b = 4''$; $D = 12''$; $t = 1{\cdot}1$; $c = {\cdot}9$; $t + c = 2$.

$$\text{By (3), Strength} = \frac{b\,D^2\,t\,c}{3\,(t + c)} = \frac{4 \times 12 \times 12 \times 1.1 \times {\cdot}9}{3 \times 2} = 95{\cdot}04.$$

If $t = {\cdot}9$, and $c = 1{\cdot}1$, the result is manifestly the same—95·04.

By equation (3), the strength varies as $\frac{t\,c}{t + c}$, and, $t + c$ being a given quantity, or of a given length, the strength varies as the rectangle $t \times c$, which, as known, is a maximum when $t = c$, as before determined.

By the expression for the strength, $\frac{t\,c}{t + c}$, the strength of different kinds of metal may be readily compared one with another, thus—

	Strength in tension in tons per square inch.	Strength in compression in tons per square inch.
Wrought iron ...	23 ...	12
Cast iron ...	8 ...	51
Copper ...	16 ...	3

If a weight be suspended from the extremity of a metal scantling projecting one inch from a wall, one inch in depth, and one-third of an inch in breadth, the absolute and relative strength of the metal scantling in wrought iron, cast iron, and copper, will be as follows:—

		Absolute Strength.	Relative Strength.
Wrought iron	$\frac{23 \times 12}{23 + 12}$	= 7·8857 ...	100·000
Cast iron	$\frac{8 \times 51}{8 + 51}$	= 6·9152 ...	87·693
Copper	$\frac{16 \times 3}{16 + 3}$	= 2·5263 ...	32·036

Cast iron being 12·307 per cent., and copper 67·964 per cent., weaker than wrought iron. In like manner the strength of timber and other kinds of metal may be found and compared one with another.

In estimating the breaking weight of a beam already broken, reference must of course be had to the *form* and dimensions of the beam, the disposition, tension, and compression of the metal, and from thence, unless shown in the fracture, the position of the neutral axis; the strength, as before found, being the greatest when the neutral axis is at the middle of the depth.

"If a beam be 34 ft. long, 8 ft. deep, and 9½ ft. thick, weighing 42 tons, be loaded with 300 tons at each end, find the strain on each square inch of the top of the vertical central section."

$$\text{By equation (3), strength} = \frac{b\,D\,t\,d'}{3\,l} = W.$$

$$t = \frac{3\,l\,W}{b\,D\,d'} = \frac{3 \times 17 \times 12 \times 310{\cdot}5}{9\tfrac{1}{2} \times 96 \times 48} = 4{\cdot}3408 \text{ tons}$$

per square inch, the tension and compression being the same.

If the tension were 8, and compression 51, then,

$$\text{by equation (2), } d' = \frac{c\,D}{t + c} = \frac{51 \times 96}{59} = 82{\cdot}983.$$

$$t = \frac{3 \times 17 \times 12 \times 310{\cdot}5}{9\tfrac{1}{2} \times 96 \times 82{\cdot}983} = 2{\cdot}5109$$

tons per square inch, the beam being rectangular, and therefore weak in form.

If the tension, compression, and sectional area of the metal in two beams were the same, one rectangular, 9½ × 96 = 912 in., the other flanged, top and bottom flanges (the tension being equal to the compression), 17 in. by 8 in., middle rib 80 in. by 8 in., sectional area 912 in., then, the strength of the rectangular beam will be to the strength of the flanged beam, as 228 to 283, the strength being increased 24·12 per cent. By a proper disposition of the metal, and observing the mechanical rule, "the strength as the stress," the strength of the flanged beam might be further increased.

In two beams, as before shown, suppose the neutral axis to be 48 in. from the top in one beam, 82·983 in. from the top in the other beam, the tension *plus* the compression 59 tons in both beams, then, the flanges being properly proportioned, and all other conditions being the same in both beams, the strength of the beam, neutral axis 48 in. from the top, will be to the strength of the beam, neutral axis 82·983 in. from the top, as 2·133 to 1—which again shows the importance of properly taking into account the tension, compression, position of the neutral axis, and strength of the metal.

I am, Sir, your obedient servant,

WILLIAM LEA, Surveyor.

3, Highgate-place, Birmingham.

Miscellanea.

Orders were promulgated at Portsmouth dockyard on Thursday for the entry of about 1,000 additional hands, 600 of whom are to be shipwrights, and the remainder of different trades and labourers.

A Frenchman has patented an invention for pulverizing the refuse of slate, and mixing with it some substance which produces a most durable material, and which answers the same purpose as some kinds of our most valuable stone.

An American paper states that a scheme is under consideration for warming houses from a central source, and supplying citizens with heat as gas is now supplied.

The process of manufacturing aluminium in use at Salyndre Works, as described by Mr. A. Stewart, has been published in a recent issue of the *Revue Universelle*. They are working a very valuable ore furnishing pure alumina by two very simple operations, which now renders the preparation of aluminium an actual metallurgical operation in the Ollionelles, near Toulon. Its average composition is—alumina, 60 per cent.; oxide of iron, 25; silica, 3; and water 12 per cent. = 100. After being pulverized under an edge-runner, it is mixed with soda-

and heated in a reverberatory furnace. The mass, although not even agglutinating, becomes changed into an aluminate of soda, and a double silicate of soda and alumina is obtained, mixed with oxide of iron, silica, and a little of the alumina which has not reacted. The aluminate of soda is dissolved out with water (the impurities remaining undissolved), and thrown in fine streams through a current of carbonic acid, by which means alumina is thrown down, and carbonate of soda remains. The precipitated alumina is separated by decantation, and washed with warm water to remove the last traces of soda. In practice no soda is lost, except a small portion converted into silicates, the remainder being recovered by evaporation. The alumina is completely dried, and is ready for final treatment. The manufacture of the sodium has been but little modified. The final reaction which yields the aluminium is effected in a reverberatory furnace. To the double chloride of aluminium and sodium is added about 5 per cent. of sodium; and, lastly, cryolite as a flux. By this means the metallic aluminium is economically and speedily obtained.

The only coal-field in India, of any considerable extent, says the *Mining Journal*, known at present, is that of Raniguni or Damooda, near Burdwan, in Bengal, covering an area of about 500 square miles. There are some 50 collieries in this field, producing yearly on an average about 300,000 tons of coal. The description produced is a variety of non-coking bituminous coal; but one great objection to that worked in the Damooda field is the presence of iron pyrites, and its consequent liability to spontaneous combustion, which render it particularly unfitted for steam ships. The broadest seam yet discovered is at Kasta, where the bed is 35 ft. thick. Next in importance to the Ranigunj field are the Nerbudda coal deposits. They are supposed to extend over an area of fully 300 square miles; but their distance at present from any available market makes the out-turn but of little practical use. As, however, iron ore is found to exist in the same locality, the coal will prove serviceable for smelting purposes, and will thus enhance the value of the iron mines. The best coal is found at a place called Mopani, where the beds have an average thickness of from 7 to 8 ft. A company has already been formed for working these coal and iron deposits, and we have no doubt that, as the railway progresses towards that part of India, the Nerbudda coal fields will afford an ample supply, at a fair profit, to the important line which in two or three years we may hope to see completed as far as Jubbulpore. No workable coal has been found in the Punjaub or north-western provinces; a few patches of lignite only have been met with. In Scinde a small mine was opened in the Lynah Valley, in 1856, by the railway company there; but, owing to its irregularity and probable want of sufficient age, it was abandoned. Neither in the Bombay nor Madras Presidencies, nor in the Nizam's dominions, is coal known to exist; and the few black shales met with on the Godavery, which are incapable of combustion, cannot be said to come under the denomination of coal. The entire quantity supplied annually by the Ranigunj, Rewan, Nerbudda, and other Indian coal-fields, does not exceed 400,000 tons. The Bombay Presidency is now, we believe, undergoing for the first time a geological examination on a systematic scale; but the strata known to prevail over the greater part of its surface precludes the idea of any good or workable coal being found.

An engineering operation of magnitude and importance is projected in the Department of Bouches du Rhone, for the execution of which the Prefect has invited proposals. The object is the formation of a canal to unite the Rhone with the sea. The cost will proably amount to between two and three millions of francs.

The advance in the price of iron has imparted a large amount of activity to the iron trade of South Wales, and all the works of the district are in full employ. Many hundreds of additional hands could be employed at both the iron and coal works, and when the establishments which are about to commence operations are in full work the scarcity of men cannot fail to be more severely felt than at present. Emigration continues, and after every pay-day at the larger works it has become quite an ordinary matter for 30 or 40 skilled hands to leave, the majority of them for the Northern States. The reports of high wages and the succes of connexions and friends are the inducements which influence the men to leave their native country. It is generally believed that the increased demand for iron, the scarcity of workmen, and other circumstances will not only keep prices up, but there is every likelihood that another rise will take place. An increase in the means of supply or over-production is one particular point to be guarded against, or else prices will certainly go down as fast as they have gone up. The following are the number of furnaces in blast and out of blast, at the present time, at the South Wales Works:—Dowlais, in blast 13, out of blast 5; Ebbw Vale, 2, out of blast 2; Victoria, 2, out of blast 2; Sirhowy, 3, out of blast 2; Abersychan, 4, out of blast 2; Beaufort, 6, out of blast 1; Varteg, 1, out of blast 1; Pontypool, 4 (all) in blast; Curnavon, 5, out of blast 2; Golynos, 1, out of blast 3; Cyfarthfa, 11 (all) in blast; Contardawe, 1, out of blast 1. There are several works also at a complete standstill.

The *North British Mail* states that permission to work a French patent for the manufacture of brandy from coal gas has recently been purchased for a large sum by an English company, and the work of manufacture is on the point of being started in London. Coal gas, as many know, is a mixture of several sorts of gases, and olefiant gas, the chief illuminating principle of coal gas, is one of these. The richer, therefore, that any coal gas is in this principle, the better fitted is it for the manufacture of spirits (brandy or whisky). Now, it happens that the coal gas made in Scotland, and in our own city, is among the very best produced anywhere, and accordingly we may expect that this new use will be quickly found for our coal gas, and that possibly the price may come to be enhanced by the circumstance. It is not our purpose to talk of the process, but we may in a word remark that olefiant gas consists of carbon (charcoal) and hydrogen, and alcohol consists of the same ingredients and oxygen. By taking away one-half of the hydrogen of the gas, and adding the proper amount of oxygen, alcohol is formed. The old joke that represented a man who was half-seas over as being "gassed," will not be found far from the truth after all.

From New Zealand we hear of a very important geographical discovery. Martin's Bay, on the west coast of the southern island, had long been known to receive a river flowing from the interior; but the river has now been explored by a Dr. Hector, found to be navigable for a great distance, to be directly connected with a considerable lake, and to bring him by water within forty-six hours' march of Lake Wakitepu. This will open up the interior of the southern island for at least 100 miles, and a settlement on Martin's Bay is very likely to eclipse Dunedin.

An offer has been made to connect the whole of the West India Islands, by telegraph, with the mainland at Cayenne, in French Guiana, and at Key West, near Florida, if a guarantee of 6 per cent. on the outlay can be obtained. The cost is estimated at £300,000.

The last brick of the subway of the new street in Southwark was laid on Thursday by Mr. Thwaites, the chairman of the Metropolitan Board of Works. The ceremony of opening the thoroughfare to public traffic will take place on New Year's Day.

Five of the arches in the new Liverpool Waterworks fell on Monday last, and fearfully, if not fatally, injured a number of the workmen.

It is understood that the Charing-cross Railway will be opened for public traffic on the 1st of January. The station at Charing-cross will probably not be finally completed before March next. The hotel at Charing-cross will not be ready for business until May or June next.

The late extraordinary passage of the "City of New York," Captain Kennedy, has created quite a sensation in nautical circles, and the abstract of her log, which was posted in the Exchange Newsroom at Liverpool, on Tuesday, was a continual source of interest. The distances travelled each day was so great, and withal so regular, that we consider them worthy of being placed before our readers. From the day she left Sandy Hook (the 12th), until noon the following day, she steamed 254 miles; on the 14th, 330 miles; 15th, 320 miles; 16th, 306 miles; 17th, 311 miles; 18th, 321 miles; 19th, 323 miles; 20th, 318 miles; 21st, to Fastnel Rock, 254 miles, arriving at Queenstown at 11.30 in the morning of that day. The mean time of the run from New York to Queenstown is eight days nineteen hours, being the fastest ever made by any screw steamer. Great interest exists as to what time the "Scotia" will be reported off Queenstown; and many confident opinions were expressed that she would arrive there in the course of Thursday (to-day).

Patents for Inventions.

ABRIDGED SPECIFICATIONS OF PATENTS.

The Abridged Specifications of Patents given below are classified, according to the subjects to which the respective inventions refer, in the following Table. By the system of classification adopted, the numerical and chronological order of the specifications is preserved, and combined with all the advantages of a division into classes. It should be understood that these abridgements are prepared exclusively for this Magazine from official copies supplied by the Government, and are therefore the property of the Proprietors of this Magazine. Other Papers are hereby warned not to produce them without an acknowledgement:—

1221. D. M. Fyfe. *Improvements in the brushes, instruments, or apparatus employed for painting the centres and bulls'-eyes of military or other targets.* Dated May 15, 1863.

For the purposes of this invention, upon a central axis, brushes are mounted on lever arms fixed on the axis, the breadth of each brush corresponding with the radius of the bull's-eye, the circle, and the space intermediate of the bull's-eye and the circle. The central axis is formed with a crank or bow, and with a rest or breast plate at one end, and pointed at the other. An open frame is connected to the central axis, so constructed as to form circular spaces or races corresponding to the surfaces to be painted, within which the movements of the several brushes are controlled in order to confine the action of each brush to the clearly-defined limits of the spaces of this frame. A countersink or recess is punched or formed in the centre of the bull's eye, and when it is desired to paint or repaint the central portions of the target (the brushes above referred to having been first supplied with paint of the colour required for each section) the point of the central axis is placed in the central hole or recess in the bull's-eye, with the open frame and brushes resting against the face of the target; the central axis is then caused to revolve by means of the crank or bow, and the several sections of the target upon which the brushes are thus caused to operate will be readily covered with paint. *Patent abandoned.*

1222. D. M. Fyfe. *Improvements in the means or apparatus employed for raising, removing, transporting, and refixing military or other targets or mantlets.* Dated May 15, 1863.

The object of this invention is to obviate the difficulty, danger, and loss of time incurred in raising, removing, transporting, and refixing heavy military or other targets and mantlets. For this purpose the patentee constructs a carriage frame of suitable strength, mounted on two or other suitable number of wheels, with shafts or other means of draught, and to the hinder part of this frame the bed or platform for supporting and carrying the target or mantlet is hinged or joined, in such manner as to be capable of being tilted or raised into a vertical position, and lowered again by suitable mechanical means. Upon the frame of the carriage a shaft or axis is mounted, and turns in suitable bearings, and on this shaft or axis one or more toothed pinions (or it may be a worm wheel) are fixed, the teeth of which engage with one or more toothed sectors fixed on the under side of the moveable bar or platform of the carriage. One or both ends of the axis of the pinions may be suitably formed for receiving the socket of a winch handle, by turning which motion is given to the pinion and to the toothed sectors, and by this means the moveable bed or platform of the carriage will be raised from its horizontal into a vertical position against the face of a target or mantlet which is to be raised and removed. To the sides and upper end of the moveable bed or platform hooks, clips, or holdfasts are attached capable of being readily caused to embrace the outer edges or flanges of the target or mantlet, so as to secure it firmly to the bed or platform. When this is accomplished, motion is again imparted to the axis, pinions, and toothed sectors, and the target or mantlet will thus be raised upon the bed or platform, which is then caused to reassume its horizontal position upon the frame of the carriage ready to be removed or transported to any other desired site. Suitable break apparatus may be applied to the pinion, axis, and to the wheels of the carriage. *Patent completed.*

1223. W. Clark. *Improvements in repeating firearms.* (A communication.) Dated May 15, 1863.

This invention relates to repeating firearms which are loaded at the breech from a magazine composed of a tube arranged below and parallel with the barrel, the said magazine containing the cartridges arranged end to end one behind another. The cartridges employed are of the kind known as fixed ammunition—that is to say, they have metallic shells, and carry their own fulminate priming; and they are carried up from the mouth of the magazine to a position in rear of the barrel by means of what is termed a carrier block working vertically within a mortise in the frame of the arm, and are afterwards pushed into the barrel by means of a sliding breech-pin, the said carrier-block and breech-pin being both operated by means of a lever arranged under the stock. The first part of the invention consists in the employment, in combination with such sliding breech-pin, of a plunger which passes through the said breech-pin, and moves with it, but which has a certain amount of longitudinal motion independent of such pin for the purpose of effecting the explosion of the fulminate priming by the blow of the hammer upon it. The second part of the invention consists in the combination with the so applied breech-pin and plunger of a rest for the support of the cartridges at the bottom, and a spring catch for taking hold of them at the top to withdraw the empty shells from the chamber of the barrel after their discharge. And the third part of the invention consists in so forming the top of the above-mentioned carrier-block that, in its rise from the mouth of the magazine to present a new cartridge in the rear of the barrel, it will strike the last discharged and withdrawn cartridge shell in such manner as to throw up the front end of the same, while its rear end is held down by the spring catch to the breech-pin end, and so to tip it over in a backward direction, and free it from the catch, and throw it out of the firearm. *Patent completed.*

1224. A. Macmillan. *Improvements in buttons, and in fastening buttons to garments.* Dated May 15, 1863.

For the purposes of this invention, in constructing buttons, whether of metal or other materials, and whether covered or not, the patentee forms each button with a stem or shank at the back, by preference of a cylindrical shape; at the back end of the stem or shank is formed an enlargement of somewhat greater diameter than the stem or shank, but still such as will pass through a comparatively small hole in the fabric to which the button is attached; and in order to assist in retaining the stem or shank from being drawn back through the hole when the button is in use, a disc of leather, vulcanized india rubber, or other suitable material, is employed; through this disc a small hole is made, the enlarged end of the stem or shank of the button is forced through it, and the disc by its elasticity embraces the stem or shank. *Patent completed.*

1225. R. T. Mallett. *Improvements in the construction of piers, walls, and other similar structures, and of landing stages, and in the constructions therewith or attachments thereto.* Dated May 15, 1863.

The patentee claims—1, the general system or mode of constructing piers, walls, and other similar solid or hollow structures, substantially in the manner described and illustrated in the drawings; 2, the application and use of the peculiar construction of continuous undersunk coffer dams, composed of iron or other metal, in combination or not with other materials, in the building of piers, embankment, walls, and similar structures, substantially in the manner described; 3, the constructing of iron or other metal coffer dams for piers, walls, and similar structures in sections of single thickness, bolted together, as described; 4, the application and use of water-tight compartments, diaphragms, or bulkheads of iron or masonry, in combination or not with other materials, between the surface of the structure and the interior of the coffer dam, substantially in the manner described; 5, the application and use in combination with the water-tight partitions, diaphragms, or bulkheads above referred to, of plates made adjustable to suit the surface of the wall or other structure, in the manner described; 6, the application and use in combination with the water-tight partitions, diaphragms, or bulkheads above referred to, of a flap of vulcanized india rubber, or other suitable material, in combination or not with adjustable plates, for the purpose of obtaining a water-tight joint, as described; 7, the system or mode of moving floating landing stages or dummies by means of their approaches only, as described; 8, the peculiar construction and arrangement of the steps or surfaces of the approaches to floating landing stages or dummies, as described. *Patent completed.*

1226. J. Patterson. *Improvements in machinery or apparatus for grinding, crushing, cleaning, and hulling or shelling various kinds of farm or vegetable produce, also applicable to the crushing or grinding of minerals and other substances.* Dated May 15, 1863.

This invention relates to that class of mills in which the grain or other substance is introduced through an eye or aperture in or near the centre of one of the stones to the space between the grinding surfaces, and is ground or otherwise operated upon in its course from thence to the periphery where it is discharged. The grinders may be of stone or steel, or other suitable material, and may be placed horizontally or vertically. They may also be placed concentrically or eccentrically to each other. The improvements consist—1, in causing both the grinders to revolve in the same direction, but at different speeds, to facilitate the discharge of the ground material, and to effect a more perfect distribution of the feed over the grinding surfaces; 2, in place of imparting to both stones a simple rotary motion on their axes, it is proposed, in certain cases, to impart a compound or twofold motion to one of them by causing it to revolve round its own axis, whilst at the same time such axis itself is made to describe an orbit round an imaginary axis. By this compound motion of one of the stones a wrenching or compound action is obtained upon the substances to be ground, or otherwise acted upon, in addition to the effect produced by the ordinary motion of millstones or other similarly arranged grinding surfaces. 3, of an improved mode of introducing the substance to be ground or otherwise acted upon between the grinding surfaces. For this purpose a recess or space is formed in the back of the stone around the spindle upon which it revolves, and as close, up to the surface of the stone as convenient, and from this recess the grain or other substance to be ground or otherwise acted upon is thrown through several surrounding openings by centrifugal force. The admission of the grain or feed is regulated by a modification of the apparatus known as the "silent feeder." The sliding-tube in this case encloses the mill spindle, and is sufficiently large to allow the grain to pass freely towards the end of the tube, from which it is allowed to escape, as the tube is drawn back from the inner end of the recess. 4, in causing both stones to revolve upon the same spindle, by fixing one of them upon the spindle and the other upon a tube which encloses a portion of the spindle, and is free to revolve upon it. 5, in an improved mode of regulating the distance between the grinding surfaces by connecting a screw on the spindle by means of wheelwork with a handle and wheel or regulator in such a way that the handle or wheel remains at rest while the spindle revolves. *Patent completed.*

1227. J. Papin, C. Lintz, and L. Lavacherie. *Improvements in the manufacture of boots and shoes.* Dated May 8, 1863.

This invention consists in prolonging the ordinary upper leather of the boot or shoe in such a manner as to form a sole and make by itself a supporter for the application of the other soles for repairs. Instead of using the small pieces of leather which in the old system form the filling up, the inventors employ a single piece of good leather which forms the sole, and is inserted into and at the same level with the prolonged upper leather. It is upon that sole, formed by the prolonged upper leather and the filling piece, that the double sole and the last sole are sewed or nailed. *Patent abandoned.*

1228. R. W., W., and T. Waddington. *Improvements in combs for combing wool by machinery.* Dated May 16, 1863.

This invention relates to improvements in the combs used in wool-combing machines, known and distinguished as Rawson's machine, in which a circular comb is employed. The object of this invention is to dispense with the backing operation, or the necessity for combing wool several times over, as practised in Rawson's machine aforesaid, and to enable the combing to be accomplished effectually at one operation. *Patent abandoned.*

1229. B. Browne. *Improvements in the manufacture of elastic material.* (A communication.) Dated May 16, 1863.

In carrying out this invention the patentee forms a die or plate with holes or indentations therein, so that the elastic material in the act of being made into sheets will have on its under side a series of points or projections. The material thus formed may be applied between the soles of boots and shoes when in use, when the weight of the body and pressure of the feet of the wearer will compress the series of points aforesaid, and produce elasticity, very much resembling that furnished by nature in the structure of the human foot. Material of the above form, when applied to the manufacture of horse collars, saddles, knapsacks, and such like articles, may be so affixed as to admit of the free passage of air between the materials, thus rendering them self-ventilating, and by thus distributing the pressure or weight on the saddle, collar, and knapsack, chafing is avoided, and the weight carried with more comfort and ease than when the above-named articles are made in the manner heretofore practised. *Patent completed.*

1230. J. Hincks. *Improvements in lamps.* Dated May 16, 1863.

These improvements are especially applicable to night lights or lamps in which volatile hydrocarbons are burned, but are also applicable to other lamps. In applying this invention to a night light or lamp, the patentee employs a flat wick, which is raised and lowered in its case in the ordinary way. In conjunction with the said flat wick he uses a deflector, having a circular opening for the flame to pass through, instead of the flat or elliptical opening ordinarily employed. He perforates the windguard with large and numerous perforations, so that there is a copious supply of air through the windguard to the under side of the deflector. The advantages obtained by these improvements are, that the length of the flame remains constant or nearly constant during a long burning of the lamp, a shorter chimney may be employed than that required in lamps of the ordinary construction, and the combustion of the oil is so perfect that it burns without odour. *Patent completed.*

1231. R. Talbot. *A folding rudder for steering barges in the river Thames or coastwise.* Dated May 16, 1863.

This invention consists in dividing the rudder in two parts, the outer part of which is caused to fold into the inner part or box, so as to shorten or reduce the length when requisite. *Patent completed.*

1232. F. M. Burns. *Improvements in preventing the fouling of the bottoms and sides of ships and vessels, particularly applicable to ships and vessels constructed of, or sheathed with, iron.* Dated May 16, 1863.

In carrying out this invention, a tank or receptacle for oil or other oleaginous substances is fitted in any convenient part of the vessel; or if iron masts be used, their interiors may be made available for containing the oil or oleaginous substances. From this tank or receptacle a pipe leads, or pipes lead, to pipes or channels on each side of the keel, or at each side of the out-water or otherwise, such channels or pipes being perforated with numerous small holes, through which holes the oil shall ooze out, and thence ascend and keep the sides and bottom well greased, which will effectually prevent the adhesion of barnacles and other marine animals and plants. Before leaving the dry dock, the inventor proposes to oil or grease the sides and bottom of the vessel. When applied to wooden ships, iron sheathing could be used with the arrangements above described, thereby obviating the necessity of using copper or other expensive sheathing. *Patent abandoned.*

1233. W. Clark. *Improvements in rotary engines.* (A communication.) Dated May 16, 1863.

This invention is not described apart from the drawings. *Patent abandoned.*

1234. J. T. Newton. *Improvements in machinery for planishing and rolling sheet metal.* Dated May 16, 1863.

According to this invention, the patentee obviates the difficulties which have hitherto prevented the use of pairs of planishing rollers of small size, by putting such a pair of rollers between two other rollers, by preference, of larger size; the axes of all the rollers are in the same plane, and the outer rollers are capable of being set up towards each other in the usual manner. By this arrangement it will be seen that, when a plate is passed between the pair of small planishing rollers, they are prevented from yielding by the outer rollers which support them throughout their whole length, and as the two small planishing rollers constantly run in contact with the outer rollers, they are ground true by them as fast as they are worn away by the plates, hence they will run for a considerable time without re-turning. *Patent completed.*

1235. J. Gibbs. *Improvements in preparing and spinning flax and other vegetable fibres and filaments, and in machinery employed therein.* Dated May 16, 1863.

This invention is not fully described apart from the drawings. *Patent completed.*

1236. W. White. *Improvements in machinery or apparatus employed in the dressing of lace or other fabrics.* Dated May 16, 1863.

The first part of this invention relates to the circular or roundabout machine of that kind in which the needle bits are moved up and down vertically in saw gates formed in an upper and a lower ring. These rings are usually made of brass; but the patentee prefers to make the upper ring of wrought iron fitted rather tightly on the inner cylinder, but so as to be capable of sliding vertically upon it, and of being at the same time carried round with it, without sliding upon it horizontally. The second part of this invention relates to the straight machine. Here the crank moves a bar which has as many drivers attached to it as there are divisions in the machine; each driver may be thrown out of gear from the bar which it drives, so that one or more breadths of work may be made at the same time, as one or more of the divisions in the machine is or are at rest; or the whole may be moved together, each bar moved by a driver causing the whole of the movements requisite to produce a looped fabric. *Patent completed.*

1237. T. O. Stretton. *Improvements in machinery or apparatus employed in dressing of lace or other fabrics.* Dated May 16, 1863.

In carrying out this invention, the patentee employs two rails which lie parallel to and over the two side rails of a dressing frame and are provided at each end with a swivel frame or bearing, each bearing carrying two pulleys or rollers which run upon the upper side of the rails of the dressing frame. Each of these bearings also carries a roller which bears against the outside of the rails. In the part of the bearings above the first-named rails a provision is made to allow of two other rails sliding within the bearings, one end of each of the two last-named rails is attached to the swivel of the bearings, and the other end of the rails slides in the other two bearings, so that as the dressing frame is narrowed or widened, the two first-named rails will be upon the rails of the dressing frame. Running upon the upper pair of rails is a pair of trucks which support a frame carrying a box or trough, to one side of which a number of stop-cocks are secured. The other end of the stop-cocks is attached to the outer one of two pipes lying one within the other. There is a cap at one end of the outer pipe which unscrews, so that the interior of the pipe may be readily washed out. The other end of the pipe has a cap attached to the inner pipe, so that the inner pipe may be turned round to regulate the flow of the starch or other "dressing" liquid placed in the trough or box above named. The outer pipe is pierced with holes through which the "dressing" flows on to a strip of flannel or other suitable material, whence it drips on to a roller which is nearly of the same width as is the distance between the upper rails. This roller is capable of being raised by a lever at either end or at both ends. When a piece of lace or other fabric has been supplied with the dressing liquid for the same length as the width of the roller, the rails and apparatus are then moved to the extent of the length so dressed, and the next length of lace or other fabric is then dressed. The roller, trough, and perforated pipe, with their appliances, are moved from side to side of the dressing frame by a handle attached to the apparatus. *Patent abandoned.*

1238. E. B. Wilson. *Improvements in the manufacture of iron and other metals, and in the apparatus employed therein.* Dated May 16, 1863.

This invention consists in a novel form of vessel and mode of treatment, by means of which the patentee is enabled to reduce, deoxidate, and purify metalliferous sands, ores, and metals, especially iron, and further to purify them and remove the various impurities, and to produce the metal pure; or to carbonify or convert iron into steel when it is under operation. The patentee effects this by dividing the vessel into two chambers by means of a diaphragm properly arranged for the purpose. The upper and larger chamber is used for reducing purposes, and this portion he calls the reducing chamber. In this the ore, metallic sands, pig iron, or other metal, with the necessary reducing agents and materials, are placed, and a blast of heated gases and atmospheric air is blown upon the materials from above until the metal is reduced to a liquid. He assists the down-blast by means of a jet or jets of steam for reasons hereafter to be described. In some cases the metals may be placed in the bottom of the chamber, and reduced by the

gases without charging the metal with the fuel. The metal, when reduced, descends into the lower portion of the reducing chamber, and passes through the diaphragm, which is supplied for this purpose with convenient perforations or passages, to allow both metal and heated gases free conduct to the lower or refining chamber. The refining chamber is of a convenient shape, and the metals being there collected, are therein exposed to the action of the flames and heated gases passing from above upon them; or if desirable, a further supply of gases or air may be blown through the side of the refining chamber upon or through the metal therein. The gases, after completing their work, are allowed to escape by any convenient exit, which may be provided with a regulator or damper, so as to regulate the current or draught. This refining chamber may also be provided with suitable inlets, so that materials or gases capable of carbonizing the metal may be injected. The reducing chamber may be provided with a manipulating door, to examine or test the iron or metal under operation, and with suitable arrangements for charging and discharging the materials. The other purposes to which this invention is applicable are such as the manufacture of glass. *Patent completed.*

1239. J. WHITEHEAD. *Improvements in motive power machinery, especially adapted for raising and forcing water and other liquids or fluids, part of said improvements being applicable to steam engines and other machines fitted with pistons.* Dated May 16, 1863.

The object of this invention is to dispense with the necessity for employing stuffing boxes in hydraulic machines, steam engines, and other machines working with pistons, and thereby to avoid or reduce friction at such parts. The patentee proposes to effect this by the following means:—The piston, plunger, or ram he forms less in diameter than the bore of the cylinder in which it works, and to the bottom of each ram he affixes a piece or pieces of leather as a tube of semicircular form inside its lower or outer edge. Inside the tube, and on a rod screwed into the bottom of the said piston or ram, he places loosely a spherical or conical-shaped piece of metal, which, when pressed against by the water, forces the edge of the leather outwards, and causes the same to fit the cylinder water-tight. He proposes to form the cylinder of a solid square piece of metal, bored out at its centre, and open at top (having no stuffing box) to receive the rams. The cylinders are fitted in an oblong cistern containing water. Two or more small pumps fitted with suitable valves are also fitted in the cistern, and the pumps are worked by cranks or eccentrics mounted on a shaft for injecting water into the square cylinders aforesaid for lifting the rams and imparting motion to a long lever, an anti-friction roller being adapted to the head of the rams upon which said lever rests. This lever has its fulcrum on a strong pin fixed in a standard, and the end of this lever is connected to the pump rod leading down the shaft of the mine, pit, or other place from which the water is to be raised; or the power may be transmitted by pulleys and bands, or spur or bevel gearing, to the machinery to be driven. In adapting the piston above described to the cylinders of steam engines, he proposes to use a band of steel, or other suitable metal, instead of leather. *Patent completed.*

1240. E. CHRISTMAS. *Improvements in carriages for common roads.* Dated May 18, 1863.

The patentee claims the use and application of a bottom side plate formed of flanged or angle iron, as described, and the substitution thereof—especially in the doorways—for the timber and timber-plated bottom sides and framing as at present used; 2, the inside door suspended and supported platform and recess construction of carriage for invalids, as described; 3, the lever and other mechanism for raising and lowering the platform and actuating the other improved parts as described. *Patent completed.*

1241. W. WATSON. *Improvements in the manufacture of bread, and an apparatus used for the same.* Dated May 18, 1863.

We cannot here give space to the detail of this invention. *Patent completed.*

1242. H. BENNETT. *Improved apparatus or mechanism to be used for facilitating the puddling of iron.* Dated May 18, 1863.

This invention consists in applying mechanism worked by steam or other power to assist the puddler in the process of puddling. The patentee accomplishes this as follows:—He has a shaft to work horizontally, endways or backwards and forwards, similar to the piston rod of an engine. This shaft can be extended to several furnaces, and to this shaft he connects a connecting rod moving a sliding piece backwards and forwards in a slide, and connected with which sliding piece he has a vertical shaft, at the top of which the puddler's rabble or tool should rest, so as to participate in the motion of the vertical shaft. This vertical shaft can be moved round to different angles by means of a ratchet motion (or mechanical equivalent) so that the puddler can guide the motion of the rabble to different parts of the furnace. By this invention a puddler will be able to work with ease a larger quantity of iron in each charge, thus effecting a saving of fuel and time. *Patent completed.*

1243. A. HEATHER and J. REDFERN. *Improvements in the construction of steam boilers for marine, locomotive, and stationary engines.* Dated May 18, 1863.

This invention has reference to a previous patent, dated February 23, 1860 (No. 495). The first improvement relates to the tube plate referred to in the specification of the patent of 1860, and consists in forming the tube plate situate at the front of the boiler angular or curved towards the side flues, instead of flat or square with the said side flues. This improvement is designed for the purpose of increasing the draught in the flues of multitubular boilers. The second improvement consists in constructing multitubular boilers with a central flue extending from back to front of the boiler. These improvements it is proposed to use with the other parts of the boiler as described and represented by the specification and drawings of the aforesaid patent. *Patent completed.*

1244. B. HEBBLEWHITE. *Improvements in machinery or mills for crushing or reducing oil cake, seeds, and other substances.* Dated May 18, 1863.

This machinery consists of a frame carrying toothed rollers between which the substance to be reduced is first passed in order that it may enter another part of the machinery, which the inventor terms a pulverizer, in pieces of such size that the pulverizer will not be liable to become choked. A hopper conducts the substance after being acted upon by the reducing rollers into the pulverizer, which consists of a closed cylinder, the inner surface of which is toothed; an axis carrying toothed arms is fitted inside the cylinder, and the outlet from the cylinder is covered or lined with wire gauze or with perforated plate. The toothed arms are made to revolve rapidly, and the substance fed in from the reducing rollers is projected against the interior surface of the cylinder, and, becoming pulverized, is driven out, when sufficiently fine, through the wire gauze or perforated plate. *Patent abandoned.*

1245. R. FENNER and W. H. HIGHT. *Improvements in envelope-folding machines.* Dated May 18, 1863.

This invention consists in arranging the parts of envelope-folding machines as follows:—The patentees attach a plunger to an arm working from a centre, which plunger works in and out of a creasing box. In the creasing box is a series of slides, which, at the proper time, run in and give the correct inclination to the flaps of the envelope. At the bottom of the creasing box is another plunger working upon a similar arm. The two arms with their respective plungers are actuated by cams on the main shaft, and the stamping is performed by a lever also worked by a cam on the main shaft. *Patent completed.*

1246. S. TOY. *Improvements in machinery for making screw rivets, nails, or pins.* Dated May 18, 1863.

This invention consists in such improvements of the machine that the inventor is enabled to produce two or more rivets, nails, or pins at one revolution of the machine. He constructs the frame and nearly all the working parts of the machine precisely as they are now built; but he employs two or more sets of cutters actuated simultaneously by the same levers, using a corresponding number of set pins. He also employs a corresponding number of dies for pressing the nails, and all worked from one lever. The cutters and dies are all fixed upon one plate of a suitable form to receive them. He also employs two or more punches to head the rivets, nails, or pins. These punches are fixed on a slide formed to suit the different centres of the several dies and cutters, the heading, when heads are required, and cutting off, being performed at one revolution of the machine. *Patent abandoned.*

1247. J. BEAUMONT. *Improvements in condensing machines for working yarns of wool and other fibrous substances.* Dated May 18, 1863.

This invention has for its object to increase the fineness of the slubbing, roving, or yarn, without diminishing the quantity of work produced on the condenser, thereby effecting a considerable economy in the manufacture. This is effected by passing the slubbing between a series of pairs of rollers and rubbers in which certain of the rollers act as bottom rollers and rubbers, and the other articles act as top rollers and rubbers. Both bottom and top rollers act as drawing rollers, and, therefore, the fibres or slubbing will be rubbed between these rollers in the process of drawing. As these rollers work one over the other, the fibres or yarn in the form of a slubbing will be drawn between them, and at the same time will undergo the process of rubbing by means of the same rollers, to which an ordinary reciprocating motion in the direction of their axis will be communicated while they are rotating on their axis. These rollers are rotated by means of toothed wheels and pinions actuated by a driving wheel connected with the doffing cylinder, the toothed wheels and pinions being of such diameter and number of teeth, and so arranged with reference to each other, that a progressively increasing rotary motion may be communicated thereto. *Patent completed.*

1248. C. BARNARD, J. BISHOP, C. BARNARD, jun., and G. BARNARD. *Improvements in lawn-mowing and rolling machines.* Dated May 19, 1863.

In constructing lawn-mowing machines in which two drums are employed, the patentees make the drums loose and free to revolve on the drum shaft, and fix two ratchet wheels (or other equivalent contrivance) fast on the shaft. These ratchet wheels are acted on by pawls attached to the drums in such manner that, when the machine is moved forward, the drum shaft revolves; but when the machine is drawn backward, the drum shaft remains stationary. By this arrangement the levers hitherto used for engaging or disengaging the drum from its shaft, are entirely dispensed with. An ordinary ratchet and spring pawl may be used; but they prefer to make the pawls silent in their action, for which purpose they attach to them a spring embracing the shaft, so that when the machine is moved forwards, the pawl is brought into contact with the ratchet wheel, and retained there, but when the machine is drawn backward, the pawls are lifted and kept out of contact with the teeth until the forward motion is recommenced, when the the pawls again come into action. To communicate motion from the drum shaft to the spiral cutters, they employ a friction wheel on the drum shaft acting upon an intermediate friction wheel (having by preference an india rubber periphery), to which there is attached a similar wheel, but of a different diameter; these wheels are carried on a stud fixed in a radial arm attached to the side frame of the machine on the drum side, and free to move up and down, and in the direction of its length, in order that it may adjust itself between the wheel on the drum shaft and a small friction pinion on the shaft which carries the cutters. They enclose this gearing in a suitable case to protect it from dirt or injury. *Patent completed.*

1249. S. RHODES. *Improvements in machinery for twisting and doubling cotton, hemp, flax, and other like fibrous materials.* Dated May 19, 1863.

This invention relates, chiefly, to the manufacture of twine and strong cord, and consists in giving a more regular twist to the strands or yarns composing the cord, and preventing what is termed in the trade "riding of strands," making the twisting distance as short as possible, that is, the distance between the flyer and the point of junction of the strands. *Patent completed.*

1250. J. EDWARDS. *Improvements in the permanent way of railways.* Dated May 19, 1863.

In carrying out this invention, the inventor fits suitable iron arms to the sides of the rails; these arms are fitted by means of bolts and nuts, or bolts and cotters. The bolts he sometimes makes hollow to get extra strength, and these bolts he applies to fasten fish plates and other parts of the permanent way. Under the arms he places a wood or other sleeper, the sleepers passing between the stay and arms, which hold them in position under the rail. He passes a brace or stay, which is fixed to the ends of the arms by bolts and nuts or otherwise, under the rail, and inside the brace he places a filling piece of any suitable material. When he uses iron sleepers which are made of angle iron cut to length, he prefers to make the sleepers answer the purpose of fish plates and sleepers combined. These sleepers he sometimes forms by carrying a thin plate of metal from arm to arm, and so saves metal. For the arms he uses T-iron with holes perforated to get the bolts in; but he does not confine himself to this plan, as the arms can be formed in many ways. Tie bars of wood or metal are passed under and bolted to the sleepers; also he applies a capping to the rails, which capping is rolled to fit the head of the rails, and is either bolted, sprung, or forced on. This capping takes the wear off the rails; and it is only requisite to renew the capping instead of the whole of the rail. *Patent abandoned.*

1251. J. H. JOHNSON. *Improvements in breech-loading firearms.* (A communication.) Dated May 19, 1863.

This invention relates to that class of breech-loading firearms in which metallic cartridges are used, whether such firearms be constructed as revolvers, carbines, rifles, or pistols, and consists in the application and use to and in repeating firearms of a cylinder or revolving charge chamber made shorter than the cartridge-case to be used therewith, and having a compound back and forward as well as a rotary motion imparted thereto, in combination with the lock, so that the lock and cylinder will slide together in a recess or recesses in the stock, which stock is permanently connected with the barrel of the firearm. The trigger in the arrangement above referred to is permanently connected with the stock, and cannot therefore be used until the lock and cylinder are slid into their proper breech-closing position. A lock-case is also employed for enclosing and protecting the lock, and serving as a guide for the cylinder whilst sliding to and from the barrel. The cartridge is fired by the percussion of a pin situate within the lock-case above referred to, such pin being acted on by the hammer of the lock when the arm is to be fired. The sliding motion of the cylinder in the recess in the stock is obtained from a lever working on a pivot at its rear end, and connected by a link with the rear end of the lock-case, whilst the rotary motion of the cylinder is simultaneously produced by a pawl and lever acting on a ratchet wheel on the base of the cylinder, and caused to operate by being drawn over a fixed stud pin in the stock, the under side of the lever being inclined or cam-shaped, so as to impart the motion required to the cylinder as it passes over the fixed stud pin. *Patent completed.*

1252. F. FENTON. *Improvements in the treatment of certain vegetable fibres for the preparation of textile materials therefrom.* Dated May 19, 1863.

This invention relates to the preparing and softening of the fibres of tallee ramee, urtica tenacissima, China grass, Assam grass, Japan hemp and flax, Shanghai hemp, and Italian hemp, with a view to the removal therefrom of the gummy and resinous matter, and to effect the perfect separation of the fasciculæ of fibres, whereby they are rendered applicable to the manufacture of fine textile fabrics, being spun either alone as long or short fibres, or mixed with wool or cotton. *Patent completed.*

1253. R. BUNTING. *Improvements in frames, tips, and bolsters used in cutlery, and in securing handles therein or thereto.* Dated May 19, 1863.

This invention consists in constructing the frames for knife handles of metal with the opening or openings for receiving a scale of ivory or other material formed with inclined sides and ends, so as to constitute a smaller aperture on the outside than on the inside of the frame. The patentee then inclines the sides and ends of the ivory or other scale to be inserted in the frame to correspond with the inclines in the sides of the aperture in the frame, and thus secures the scale from getting out of the frame. Or where the scale to be inserted is capable of being rendered plastic, he runs or presses it into the frame from the inside. Two frames are united to constitute one handle. *Patent completed.*

1254. H. J. OLDING. *Improvements in treating flax and other fibrous plants in order to prepare the fibres thereof for spinning.* Dated May 19, 1863.

Here the patentee takes the flax or other fibrous plant in a green state, or in any other condition, and after the [illegible] has been separated, he proceeds as follows:—For gre[illegible] he passes it through a machine formed with two pairs of rollers or cylinders, the surface of whic[illegible] formed with a series of diagonal intersecting [illegible] presents the flax or other fibrous plant wit[illegible] parallel with the axis of the rollers, and pass[illegible] them in that position. The action of the roller[illegible] the boon without injury to the fibres. Whe[illegible] dry, he passes it in the ordinary manner [illegible] rollers and between other rollers having a [illegible] jogging as well as rotary motion, whereby m[illegible] bruised by the first rollers is shaken out by [illegible] plant is now ready for the next part of the [illegible] consists in steeping the plants in vats or [illegible] with covers to be used or not according [illegible] The vats are charged with a liquor, [illegible]

impregnated with lime, sulphur, and manganese, or either or any two of these materials. The plant is allowed to steep in this liquor for an hour or two, more or less. The plant is then subjected to a similar liquor, but of such strength only as to reduce leaves of turnips, swedes, or other like leaves which are placed therein to a pulpy state, and to precipitate the colouring matter to the bottom. The plant is afterwards removed and subjected to a stream of clear water. The liquor and dissolved portion of the plant issues from the vat through a valve or cock, and runs into a pool or other receiver. After the washing, he takes the fibres and dries them by any ordinary means, or by passing them through two or more pairs of rollers, and subjecting them to the action of reels or fans constructed of hollow tubes acting alternately on the fibres, and made to drive warm or heated air into and among the fibres, whereby the fibres are finally dried, separated, and freed from boon and foreign matters. *Patent completed.*

1255. J. KELLY. *Improvements in the treatment of peat or turf, and the manufacture thereof into charcoal and other fuel.* Dated May 19, 1863.

We cannot here give space to the details of this invention. *Patent abandoned.*

1256. A. PARKER. *An improved apparatus for saving from destruction by fire persons and property in houses, buildings, and ships, and also for ventilating ships.* (A communication.) Dated May 19, 1863.

In carrying out this invention, as applied to houses and buildings, the patentee fixes in a suitable position gun barrel or other tubing or piping, varying in size as may be requisite, according to the size of the building, such tubing or piping bending through the wall where necessary, and being carried up to the roof and along the tie beam to the kingpost from one end of the roof to the other, such tubing being plain, and stopped at the ends with screw-stop ends. From this tubing or piping branches of plain pipe are to proceed from the kingpost up the struts, and from thence to branch off and be fixed to the purlins, which pipe is to be perforated with three or four rows of holes in a zig-zag direction, being one on each side going from end to end of the roof; each end of this pipe is to have perforated bends screwed to the same, and brought across and connected with the pipes opposite, which are also to be perforated. If the roof is small, one perforated pipe in the centre will be sufficient. In public buildings or places of worship with galleries of one or more tiers, pipes should descend through the ceiling, and turn round the cornice on the outside of the flowers or centre pieces, and be perforated with three or four rows of holes, leaving two or more inlets from the large pipe above. Branches of plain pipe are to be connected with the main pipe in the roof, and to descend through the ceiling, and be attached to perforated pipes fixed above the gallery on the ceiling. This pipe may be classed as a member of the cornice or branched across to the outside of the gallery, playing its water upon the body of the building or gallery. The pipes for quenching the fire in the staircases should be connected by branches with the pipe above, and be fixed on the wall above the staircase, and be perforated as above described. A small ring of perforated tubing fixed on the ceiling with the water brought from above is sufficient to thoroughly saturate a room in a few seconds. Stop cocks are to be placed in the different parts of this apparastus so as to prevent a waste of water where it is not required, but these cocks should always be left open in case of emergency. Force pumps should be fixed in a suitable position, and connected with the main ascending pipe or tubing, to force the water through it. Domestic water-tanks, placed high in the building worked by valves and connected with the plain pipe in the roof, may be made available for the supply of water to the perforated pipes or tubing in the lower parts of the building; or the supply may be had from the public water main, which should be connected with the ascending pipe on the wall, or where the same may be fixed. *Patent completed.*

1257. L. CHANDOR. *An improved mechanical lamp.* Dated May 19, 1863.

This invention relates to a novel construction of lamp in which volatile hydro-carbons are burned, and consists in suppling air to the wick by mechanical means. To this end a fan or ventilator is mounted in the interior of the lamp, and rotary motion is communicated thereto by means of a strong spring and clockwork. *Patent abandoned.*

1258. T. P. SALT. *Improvements in the manufacture of trusses.* Dated May 19, 1863.

This invention consists—1, in forming the spring in trusses used for inguinal hernia in two parts, the one sliding on the other, so that the spring may be extended or contracted in front, the two parts of the spring being secured together by binding screws. The sliding end of the spring is curved upwards and outwards, the exact curve being adopted which conforms most nearly to the the line of the abdomen, and would bring the pads directly over the inguinal openings. The opposite end of the spring which presses on the spinal column is provided with two revolving circular pads instead of one, thus preventing any inclination to tilt or work out of the horizontal line. The pads are attached to the front part of the truss by a small hook-shaped spring, one limb of which is connected by binding and adjusting screws to the front part of the truss, and the other limb secured by a central screw upon which the pads rotate. 2, The invention refers to improvements in the manufacture of pads for all descriptions of trusses, and it consists in forming such pads of thin shells or blanks of metal, horn, or other suitable material, and covering such blanks with material of any required description, in manner similar to that in which Florentine buttons are made. The blanks when not formed of metal may be edged with it to afford the means of securing the covering; and for the purpose of obtaining a soft surface or cushion on the face of the pad between the covering and the shell, the patentee places spongio-piline, or other suitable stuffing. He thus dispenses with all sewing, and obtains a light and strong pad with an even surface. *Patent completed.*

1259. L. CHANDOR. *An improvement in lamps.* Dated May 19, 1863.

The object of this invention is to improve that class of lamps in which kerosene or volatile liquid hydrocarcons are burned. The improvement consists in adapting to the lamp a tube of sheet metal, or other suitable material open at both ends, and of somewhat greater diameter than the wick tube. The lower end of this tube is placed at or near the top of the wick tube, and its upper end extends above the wick tube so as to encircle the lower part of the frame. By means of this heated tube the atmospheric air will be continually consumed and replaced by fresh atmospheric air, the oxygen of which by mingling with the escaping gases of the flame (which are mostly carbon compounds) will produce a more perfect combustion. A short tube is placed around the top of the wick tube, and is attached to the holder which supports the metal air-heating tube above mentioned, so that, by merely raising or depressing the upper or air-heating tube, the light may be increased or diminished at pleasure. The metal air-heating tube first mentioned is attached to the holder by a hinge, spring, or any similar contrivance, so that the metal tube may be conveniently turned on one side to permit of the lamp wick being trimmed. *Patent abandoned.*

1260. W. SMITH. *Improvements in transferring plain or coloured prints or designs to wood or other surfaces.* Dated May 19, 1863.

This invention relates to a new mode of transferring coloured or plain prints or designs to and upon dark, variegated, or light-coloured wood, or other surfaces, and consists in covering all parts of the print or design over with opaque white colour, made up with oil and varnish, and then pursuing any of the usual modes of transferring. *Patent abandoned.*

1261. H. WREN and J. HOPKINSON. *Improvements in the construction of self-lubricating bearings for shafts and axles.* Dated May 20, 1863.

This invention relates to the kind of lubricator for which letters patent were granted unto Adolph Mohler, dated February 2, 1854 (No. 261), and consists in a mode of ensuring a more copious and regular distribution of oil over the upper surface of the shaft or axle. For this purpose the patentees employ a plate or projection supported by the upper part of the plummer block or bearing, and the said projection or plate arrests the course of the oil brought up from the reservoir by the collar, and causes it to flow upon the working surface of the neck. *Patent completed.*

1262. J. COIGNARD. *Certain improvements in sewing machines.* Dated May 20, 1863.

This invention is not described apart from the drawings. *Patent completed.*

1263. W. J. C. LANG. *Improvements in the manufacture of certain articles to be used for preserving life at sea and other purposes.* Dated May 20, 1863.

In carrying out this invention, the inventor constructs carpet bags, and other bags used for travelling purposes, when made wholly or in part of flexible material, with one or more air-proof chambers made wholly or in part of flexible air-proof material. These chambers, or the chamber when one only is employed, may be filled with air at convenience for the purpose of a life preserver, suitable valves being employed for the ingress and egress of the air. The air-proof chambers may be affixed to the sides or bottom of the bag, or may form the division itself that is generally used in carpet bags. *Patent abandoned.*

1264. P. ADDINGTON. *Improvements in the manufacture of varnishes.* Dated May 20, 1863.

This invention consists in the construction of varnishes applicable to the uses of railway and other carriage builders, house decorators, paper stainers, enamellers, oiled baize and leather or varnished cloth makers, and all or any other purposes to which gum or resinous varnishes are ordinarily applied, to be as follows:—The patentee proposes to manufacture the said varnishes by the following method, viz., by fusing gums, resins, or resinous gums, viz.:—gum amber, gum copal, gum amine, gum damar, gum kowrie, gum resin, gum asphaltum, in proportion as follows: gum, 80 lbs.; oil, 20 gallons; petroleum, 20 gallons, in copper, iron, or plated vessels, at a temperature varying from 400 deg. to 700 deg. Fahr. The gums or resins being in a state of fusion, the patentee introduces or mixes clarified oils, viz., either linseed, nut, poppy, or sunflower oil, the gum or resin and oil being mixed or combined. The patentee employs as a vehicle rock oil or petroleum spirit, either crude or the rectified petroleum of commerce, or crude petroleum refined in a certain manner, instead of spirits or oil of turpentine. *Patent completed.*

1265. R. R. JACKSON and W. PEMBERTON. *Improvements in looms for weaving.* Dated May 20, 1863.

This invention relates to a system or mode of putting strain or tension upon the yarn or warp in looms for weaving, and it consists in the application of frictional arrangements to the yarn or warp itself, instead of applying friction to the axis of the warp beam; or it consists in the combination of friction and weight applied to the yarn directly, or to the apparatus acting upon the yarn; or it consists in causing the yarn from the beam to pass over an edge or rod, then under a roller covered with elastic material, then over another edge or rod, and then on to the healds. *Patent abandoned.*

1266. T. WILLIAMS and I. NAYLOR. *Improvements in paper spools or tubes used in spinning and doubling machines.* Dated May 20, 1863.

According to the present invention, each paper tube has affixed all round one end a projecting flange. These spools are placed on bobbins which are put on the spindles of spinning or doubling machines, and have yarns or doubled yarns wound thereon, but in place of the cops being wound conical at each end, as has heretofore been the case in winding a yarn or a doubled yarn on to a paper tube, the winding at that end where the flange is formed or applied may extend to a diameter as large as the flange, whilst the winding at the other end will be conical, as before, when using paper tubes without flanges. By these means a paper spool or tube may be made to contain a much larger quantity of yarn or of doubled yarn than heretofore. *Patent abandoned.*

1267. J. C. MARKALL. *Improvements in machinery for the working of wood.* Dated May 20, 1863.

We cannot here give space to the details of this invention. *Patent completed.*

1268. J. CASSELL. *Improvements in the treatment of mineral oils and hydro-carbons.* (A communication.) Dated May 21, 1863.

This invention is carried out as follows:—After the mineral oils and hydro-carbons have been, in preference, first heated with sulphuric acid and alkali in the usual way, the inventor introduces them into a still, heated by the naked fire, or by superheated steam, and adds to them from 1 to 10 per cent. (the quantity depending upon the nature of the oil to be treated) of a mixture composed of the bichromate of potash and caustic soda, in preference, in the following proportions:—one part of bichromate of potash and two parts of caustic soda, at 36 degrees. He then distils them. Potash may be substituted for soda; and instead of bichromate of potash and caustic alkalies, he applies any of the salts of chromium, alone or in combination with the alkalies, caustic, or otherwise, although he prefers those stated above. After this distillation the oils may be treated as before with sulphuric acid and water. *Patent completed.*

1269. G. R. HARDING. *Improvements in the means of transmitting power on railways worked by vacuum or the pressure of air.* Dated May 21, 1863.

The patentee claims—1, the improvements set forth in the valve or means of transmitting power on railways worked by vacuum, and the form and mode of connecting the parts of the apparatus employed for such purpose, as set forth; 2, the use or employment of blocks or pieces of material having sides angular or converging towards each other, for the purpose of fitting into a V-shaped trough, and having also in relation to the longitudinal axis of the tube and the trough in which the blocks are fitted angular faces or fitting and bearing surfaces, by which the greater the atmospheric pressure or the better the vacuum the more perfect contact is ensured between the working parts of the apparatus; 3, the construction of flexible bars or valves, as described, for closing the communication between the external atmosphere and the interior of the tube of an atmospheric railway. *Patent completed.*

1270. W. WALKER. *Certain improvements in looms for weaving.* Dated May 21, 1863.

This invention is not described apart from the drawings. *Patent completed.*

1271. J. STEART. *Extracting the fibre from zostera marina and other aquatic vegetable productions.* Dated May 21, 1863.

In carrying out this invention, the inventor submits the plant or weed to various degrees of pressure, by means of rollers or otherwise, for the purposes of bruising or loosening the outer sheath or skin and the saccharine matter. He then places it in a wash bath of fresh cold water, for the purpose of removing all external impurities. It is then treated in a bath being a preparation of fish and water, or other animal extract, denominated a pure bath, at a high temperature, for a suitable length of time; and lastly, to pressure and friction, while in the pure bath, at the same temperature. By this process the outer sheath or skin of the plant or weed is decomposed and removed, leaving the fibre in an uninjured state. It is then dried and cleansed, and fit for manufacturing purposes. *Patent abandoned.*

1272. W. NUNN. *Improvements in the construction of signal lanterns or lamps.* Dated May 21, 1863.

The patentee claims—1, the combination of the anchor or uncoloured lantern or lamp in its complete and perfect form, as ordinarily employed, with a shell or casing containing coloured glasses, through which its light may be shown when required, substantially as described; 2, the construction of a lantern or lamp to answer the combined purposes of anchor and sailing lantern or lamp, in which combined lantern or lamp the usual uncoloured lantern or lamp constituting the anchor light in its complete and perfect form, as usually employed, is (when the whole combined lantern or lamp is required to be made use of for sailing purposes) passed into or partly into and partly outside of the shell or casing containing the coloured glass or glasses, so that the light contained within such anchor lantern or lamp may be shown or displayed through such coloured glass or glasses, and that the entire combined lantern or lamp may, when in that position, occupy a proportionately diminished space, substantially as described; 3, the use or employment of glasses or lenses double convex in vertical section, and constituting an entire or continuous circle or segment, or segments of such circle, in plan, and having each horizontal section of such circle or segment or segments parallel or of equal thickness throughout; 4, the use or employment of flat and segmental burners having a central space, whereby air is admitted upward to the inner side of the wick in the same manner as, or nearly in a similar manner to, that usual with the ordinary circular argand burner, substantially as described. *Patent completed.*

1273. F. P. WARREN. *Improvements in attaching copper or other sheathing to iron vessels.* Dated May 21, 1863.

For the purposes of this invention, the patentee first covers the parts of the vessel to be sheathed with a coating of fibrous or other non-conducting material, in order to insulate the iron of the vessel, or which may be attached thereto, or connected therewith, from the metal or composition of metals constituting the sheathing. In order to attach this coating of fibrous or other non-conducting material, he prefers, firstly, to roughen the surface of the iron, either by milling or otherwise, so as to increase the holding effect of the adhesive material or composition employed for holding or attaching the non-conducting material to the

vessel, and which may consist either of pitch or any other suitable substance or composition. A second coating of fibrous or other non-conducting material may then, if required, be similarly attached by adhesive material to the sheathing plates intended to be applied to the vessel, the inner surfaces of such plates having been first roughened by milling or otherwise to increase the adhesion of the non-conducting material to them. In proceeding to apply the plates of sheathing, beginning at the upper row thereof, he drills the plates intended to be joined together near to their edges with corresponding rows of holes, and successively attaches them to each other upon the coating of non-conducting material attached to the vessel, by means of the split or bent nail or rivet hereinafter described, the plates of sheathing being successively attached to the coating referred to by means of any suitable adhesive substance. The form of the nails or rivets employed is such as to cause them, on being passed through the holes drilled or punched around the edges of the plates and driven home, to become (on coming in contact with the non-conducting material attached to the vessel) turned out or clenched so as to hold the plates firmly together. *Patent completed.*

1274. E. T. Hughes. *Improvements in breech-loading firearms, and in cartridges connected with the same.* (A communication.) Dated May 21, 1863.

These improvements relate to firearms to be loaded at the breech, for which purpose the inventor unites the barrel or barrels solidly to the breech by means of screws, wedges, or other appropriate means; and at the rear of the barrel, and in a line with the same, he places a rocking conduit or feeder hung on a centre placed below the said conduit, and capable of assuming two different positions. The first is for the purpose of loading, in which case the end nearest the barrel is tilted downwards, its lower surface on which the cartridge rests presenting itself thus in one continuous line with the bore of the barrel, so that the cartridge can be easily pushed from the conduit into the barrel. The second is for receiving the force of the explosion, in which case the end nearest the barrel is raised sufficiently to close completely the aperture of the barrel, and thus offer effective resistance at the moment of the explosion. Another improvement relates to the construction of the lock, which consists in a tumbler provided with a hammer or needle placed below the barrel, and which can be cocked by a motion of the finger, and discharged by a trigger in the usual manner, the hammer or needle penetrating through a small aperture in the under side of the barrel to enable it to reach the fulminate of the cartridge. The main spring actuating this tumbler is also placed under the barrel, and in a line with the same. Another improvement consists in a cartridge containing fulminate powder, ball, and wad, built on a central stem or core, one extremity of which is fixed to the projectile, whilst the other extremity is provided with a small protruding metallic tube charged with fulminating powder, the explosion of which effected, the hammer above mentioned causes the ignition of the charge of powder which is placed round the said central stem or core, and covered externally with paper, linen, or other appropriate material. *Patent abandoned.*

1275. N. J. Amies. *Improvements in the manufacture of elastic webbing.* Dated, May 21, 1863.

This invention consists in the employment and use of a tape, band, or flat length of india rubber, instead of a number of strands, and in covering such flat length with silk, worsted, cotton, or other fibrous materials, by means of a circular braiding machine, this being a more economical method. *Patent completed.*

1276. A. Thomalley. *Improvements in brick kilns.* Dated May 21, 1863.

According to this invention, it is proposed to construct the kiln with a number of flues which convey the smoke and sulphurous vapours to a tall chimney built at any convenient distance from the kiln. In some cases, two or more kilns may be combined with one chimney, so that when one kiln is burnt out, the waste heat may be passed through the other, which has in the mean time been made ready for firing, thus preparing and drying the bricks before burning. This invention may be readily applied to an ordinary brick kiln, by having a flue or flues built upon the top of the kiln, and communicating by lateral flues with each other, a descending flue at the side or one end of the kiln receiving the smoke and vapours from the top flues, and carrying them off to a tall chimney. *Patent abandoned.*

1277. W. H. Clapp. *Improvements in rails or holder for coats, &c.* Dated May 21, 1863.

For the purposes of this invention, the patentee employs two brackets, by preference of metal, made to resemble ordinary hat pegs, and they have at their ends notches. In conjunction with these brackets, a rail is employed, by preference made of wood, but with metal fittings at the ends. These end fittings each consist of two discs or flanges with, between them, a piece shaped to fit the notches in the ends of the brackets. The outermost disc is not fixed, but screws on to a stem projecting from the innermost disc. The coat or other article to be held is folded and placed over the rail; this is then put into its place on the brackets, the ends of the brackets entering between the flanges at each end of the rail, and as the rail at these parts fits the ends of the brackets, it is held securely so that it cannot turn, otherwise the coat or article might run off. The rail can be secured by screwing up the two outer discs, so as to clip the ends of the brackets, and for convenience their screws are made right and left handed, so that to secure the rail they may both be required to turn the same way, either towards or from the person using the article. The rail may also be held on suitable supports formed on the brackets near their root, or where they spring from the wall or partition, and the brackets can then be used as hat pegs. The screw discs cannot come off the stems, as these are rivetted over to retain them. *Patent completed.*

1278. E. Sonstadt. *Improvements in the manufacture and purification of the metal magnesium.* Dated May 21, 1863.

The peculiarities of this apparatus and process of distillation of metallic magnesium are, that the apparatus is made of iron, and is closed air-tight during the distilling process; that the air is excluded by filling the apparatus with hydrogen before the commencement of the distillation; and that the second vessel or receiver is placed immediately beneath the fire bars of the furnace which heats the first vessel, or that which contains the crude metal, so that this second vessel may, when required, be heated sufficiently to keep the magnesium which distils over in a fused or liquid state: and so that the pipe connecting the two vessels may be kept sufficiently hot to prevent the condensation of magnesium in it. *Patent completed.*

1279. J. Fawcett. *Improvements in the preparation of food for cattle, horses, &c.* Dated May 21, 1863.

This invention relates to an improved method of preparing vegetable material for provender or food for horses, cattle, sheep, or pigs, by cooking such substances in a steam apparatus, and preparing the same for pressing into loaves, blocks, or cakes, or for grinding, mixing, and for granulating, so as to be specially adapted for horse corn to be used instead of crushed oats and beams. *Patent completed.*

1280. J. Goodman. *Improvements in velocipedes, and in the construction of wheels for the same and other carriages.* Dated May 21, 1863.

These improvements in velocipedes consist in connecting treadles and hand levers to the cranked axle to which the main wheels of the carriage are fixed, and in arranging handles to the hand levers, which, through chains or cords, communicate with the fore carriage in which the guide wheel is fitted, and turn it in any direction required for guiding the carriage. The improvements also consist in mounting the axle of the guide wheel in a groove or slot made in or applied to the sides of the fore carriage. The improvements in wheels consist in the following arrangements. The patentee introduces the outer ends of the spokes in the felloe (where felloes are used), or direcly in the tyre. He forms the hub or nave in two parts—one consisting of a ring, collar, or flange, carrying an inclined ring, which is inserted under the inner ends of the spokes, and of an outer ring or flange. The driving in of the inclined or conical ring, tightens up the spokes, and the parts of the nave are secured by screws or bolts. *Patent completed.*

1281. R. A. Brooman. *Improvements in breech-loading ordnance, breech-loading and other arms.* (A communication.) Dated May 21, 1863.

This invention is not described apart from the drawings. *Patent completed.*

1282. W. Snell. *Improvements in butt hinges.* (A communication.) Dated May 22, 1863.

This invention is not described apart from the drawings. *Patent completed.*

1283. C. Maschwitz. *Improvements in stoppers or bungs for closing or stopping bottles, jars, &c.* (A communication.) Dated May 22, 1863.

This invention consists in making stoppers or bungs for closing or stopping bottles, jars, and other vessels, and the muzzles of rifles, and for other like purposes, capable of being made to contract and expand in diameter in that part of the stopper or bung which fits into the opening to be closed. *Patent abandoned.*

1284. T. A. Blakely. *Improvements in ordnance.* Dated May 22, 1863.

This invention consists in constructing cannon and other ordnance of an inner tube or barrel of brass, bronze, or other suitable alloy of copper, with a jacket of steel. This jacket may be in one or more pieces, or may be composed of a series of separate hoops. The invention further consists in forming the barrels of two or more tubes, an inner tube of mild steel, with the outer tube or tubes of harder steel, the steel being increased in hardness the farther it is removed from the centre. In some cases the outer tubes are in the form of rings. *Patent completed.*

PROVISIONAL PROTECTIONS.

Dated September 10, 1863.

2230. T. B. Jordon, Milton Cottage, South Lambeth, mechanical engineer. Improvements in granulating and drying gunpowder, and in apparatus to be used therefor.

Dated October 8, 1863.

2470. J. Mead, Abridge, Essex. Improvements in the construction of various articles of furniture.

Dated October 19, 1863.

2554. W. Fletcher, Gloucester, gunmaker. Improvements in the construction of breech-loading firearms.

Dated November 4, 1863.

2734. M. Luneau, 60, Boulevart de Strasbourg, Paris, military collar manufacturer. Improvements in the manufacture of hat or cap frames.

Dated November 11, 1863.

2799. J. Smith, Cheetham, Manchester, dyer and finisher. Improvements in machinery for finishing or beetling woven fabrics, which improvements are also applicable to fulling machines.

Dated November 12, 1863.

2814. J., J., and J. Booth, Rodley, near Leeds, engineers and copartners. Improvements in guy cranes and other similar cranes.

2820. D. Ford, Islington, engineer. Improvements in propelling boats and barges.

Dated November 14, 1863.

2840. H. Gladstone, 2, Butler's-terrace, Ossory-road, Old Kent-road, cartridge manufacturer. Improvements in the manufacture of skin cartridges.

Dated November 16, 1863.

2892. E. C. Nicholson, Fenchurch-street, manufacturing chemist. Improvements in the manufacture of colouring matters suitable for dyeing and printing.

Dated November 19, 1863.

2896. W. B. Adams, Holly Mount, Hampstead, engineer. Improvements in wheels, tyres, axles, and axle boxes, and modes of applying them.

2897. J. Eglin, Glasgow, engineer. Improvements in "drifts," and in apparatus for making the same.

2902. W. H. Gray, St. Austell's, Cornwall, engineer. Improvements in the construction of blast cylinders, and also in the form and method of working the valves of the same.

Dated November 20, 1863.

2917. C. Stevens, 31, Charing-cross. An improved hoisting and lowering apparatus. (A communication.)

2925. W. E. Newton, 66, Chancery-lane, civil engineer. Improvements in the means of, and instruments for, attaching tags or labels to bales or packages of merchandize. (A communication.)

Dated November 23, 1863.

2943. C. Howard, 23, Stanley-terrace, Deptford. An improved watch case pendant, applicable also to other articles.

Dated November 27, 1863.

2978. J. A. R. Main, 5, Renfield-street, Glasgow, gentleman. Improvements in the mode of connecting and sustaining the intersecting bars of iron fences, hurdles, gates, and other analogous structures.

Dated December 2, 1863.

3022. R. Lublinski, 183 and 185, City-road, stick manufacturer. A new method of bending the reverse ends of partridge canes, and bending partridge canes without roots.

3024. T. Snook, 25, Wilson-street, Stockport-road, Manchester. An improved apparatus for causing a stronger and better draught or current of air so that house fires may be lighted or kindled in a very short space of time, for effecting a very considerable saving in fuel, and for throwing the heat from such fire into the building or room.

3025. J. Dales, New-inn, Strand, engineer. Improvements in fitting moveable or travelling frames and surfaces.

3026. J. Capper, Waterloo, near Liverpool, accountant. Improved apparatus for curing smoky chimneys, and preventing down draughts therein.

3028. T. T. England, Colne, Lancashire, cotton spinner. Improvements in lubricating the shafts of the conducting pulleys of mules, which improvements are also applicable to machinery in general.

3029. H. Holdrege, engineer, Irvington, United States. Improvements in the process and manner of making gas for illuminating, heating, and other purposes, a part of which may also be applied to the production of metallic oxides. (A communication.)

3030. S. Trotman, 11, Albert-street, Camden-town, engineer. Improvements in the manufacture of soap.

3034. T. Harrison, Tudhoe, near Ferry-hill, Durham, mechanical engineer. Improvements in machinery for cutting coal and other minerals and stones.

3035. H. D. P. Cunningham, Bury, Alverstoke, esquire. Improvements in reefing and furling topsails, topgallant sails, and royals.

3036. C. Langley, Deptford, shipbuilder. Improvements in the construction of ships of war and other vessels.

3038. C. Cammell, Sheffield, steel manufacturer, and W. Crompton, Openshaw, mechanic and smith. Improved railway crossings adapted to the ordinary single or double headed rails.

Dated December 3, 1863.

3043. E. Stevens, 4, Warwick-villas, Canonbury. Improvements in apparatus used when cooking.

Dated December 4, 1863.

3047. R. Riley, Sharples, near Bolton, manager. Certain improvements in carding engines.

3051. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in working railway brakes. (A communication.)

3053. T. Douglas, South Audley-street, Grosvenor-square. Improvements in the construction of combs for the human hair.

Dated December 5, 1863.

3057. W. Gorman and J. Paton, Glasgow. Improvements in obtaining and applying heat, and in apparatus therefor, being also in part applicable for lighting.

3063. J. A. Wanklyn, London Institution, Finsbury, chemist. Improvements in the production and manufacture of certain yellow and orange colours. (A communication.)

Dated December 7, 1863.

3065. A. J. Aspinall, Tue-Brook, near Liverpool. An improved hand stamp or seal for marking or impressing consecutive numbers or figures.

3067. A. Antill and W. Wilkinson, Birmingham, jewellers. An improved mode of manufacturing joints and catches for brooches and other articles of jewellery.

3069. F. Piercy, Glenadon-house, Dockmouth, Devon, artist. Improvements in the application of heat to water and other fluids, and in apparatus for the same.

3071. M. Turnor, Birmingham, metallic pen manufacturer. Improvements in pencil cases and holders for crayons and other marking, writing, or drawing materials, and in boxes for holding leads for pencils, crayons, and other articles.

3077. C. Brown, Leicester, mechanic. An improved manufacture of elastic bands, applicable to the production of ladies' skirts or crinolines.

Dated December 8, 1863.

3079. W. Wanklyn, Albion Mills, Bury, cotton spinner. Improvements in the construction of machinery for ginning cotton.

3081. J. H. Brierley, Beech Hill Mills, Halifax. Improvements in buckles for brace and other dress fastenings.

3087. T. A. Blakely, Montpelier-square, late captain Royal Artillery. Improvements in projectiles for ordnance, and in loading and firing ordnance.

3089. P. H. Desvignes, Lewisham, gentleman. Improvements in apparatus for exhibiting dissolving views.

3091. H. Eastwood, Elland, machine maker, and B.

Matthews, mechanic. Improvements in machinery or apparatus for carding wool or other fibrous substances.

3095. W. McIntyre Cranston, 77, Upper Thames-street. Improvements in reaping and mowing machines. (A communication.)

3099. A. V. Newton, 66, Chancery-lane, mechanical draughtsman. Improvements in the mode of, and apparatus for, preparing cork stuffing for mattresses, pillows, cushions, and other articles, and in the mode of applying the cork stuffing thereto. (A communication.)

Dated December 9, 1863.

3101. H. Audinwood, Weston-upon-Trent, Derbyshire, engineer. Improvements in raising or removing grain from one place to another.

3105. J. Wright, Dudley, Worcestershire, engineer. Improvements in furnaces, fire-grates, and fire-bars.

3107. T. V. Morgan, Battersea Works, crucible manufacturer. Improvements in the treatment and purification of plumbago for the manufacture of crucibles, and other fireproof articles, and in apparatus employed therein.

3109. M. Hillary, Andover, contractor. Improvements in fastenings for doors.

PATENT APPLIED FOR WITH COMPLETE SPECIFICATION.

Dated December 9, 1863.

3103. W. H. Cole, 52, Gracechurch-street, merchant. Firstly, for casting steam cylinders of steam engines in the form of a segment of a cylindrical ring or circle; and secondly, for the machine for boring them truly cylindrical, and retaining the line of the bore on the curve of a true circle. (A communication.)

NOTICES OF INTENTION TO PROCEED WITH PATENTS.

From the *London Gazette*, December 22, 1863.

1977. D. W. Barker. Shuttle boxes.
1978. J. T. King. Distributing gas.
1979. W. B. Haigh. Saw-frame.
1985. Sir J. S. Lillie. Revolving battery.
1990. R. Canham. Moulds for casting.
